3:00PM A01.00001 Numerical Predictions of Spray Root Location, Hydrodynamic Pressure, and Structural Deformation of a Highly Flexible Deforming Wedge During Vertical Water Entry  
John Gilbert, Christine Gilbert, Virginia Polytechnic Institute and State University — Wave interactions with high-speed planing craft result in repeated slamming events that can lead to equipment failure and serious injury. Our earlier efforts investigated this problem through the use of wedge drop experiments and theoretical predictions, focusing on the effects of linear-elastic structural response on spray root propagation and hydrodynamic pressure. In the current work, predictions from a coupled, non-linear finite element - non-linear boundary value approach are used to extend our previous study to include the effects of large structural deformation. Observations from recent flexible wedge drop experiments conducted at the Virginia Tech Hydroelasticity Laboratory are used to inform the development of the solver. Numerical predictions for spray root location and hydrodynamic pressure as a function of time show good agreement with experiments, while predictions for the structural deformation show discrepancies. This work is part of a larger research effort aimed at understanding this fluid-structure interaction problem.

3:13PM A01.00002 Effect of convexity & texture on the water entry of a cone; inspired by diving birds  
Lianxia Li, Mark Fenn, Maysam Mousaviraad, University of Wyoming, Christine Gilbert, Virginia Tech — Fluid-structure interaction (FSI) problems are complex in nature, especially when the loading by the fluid is unpredictable and impulsive or when the material properties of the structure are nonlinear or otherwise complex. The purpose of this study is to investigate the water impact hydrodynamics/hydro-elasticity of flexible bodies through computational and experimental methods. Computational FSI capability is developed at University of Wyoming based on a two-way coupled approach. The flow is resolved by URANS CFD modeling and non-linear FEM equations are employed for structural dynamics. Slaming experiments are carried out at Virginia Tech for a 20 degree angle aluminum wedge with a bottom plate thickness of 3.175 mm and drop heights ranging from 0.9 to 38.1 cm. Measurements include time histories of vertical position, acceleration, pressure, and strain. Strain measurements are taken at single points using strain gauges as well as full-field measurements of all strain components and out-of-plane deflection using stereoscopic digital image correlation (S-DIC). Computational studies include validation and investigations of the physics involved in the interactions. Next step will extend to highly flexible structures where the two-way nonlinear interactions are more significant.

3:26PM A01.00003 Fluid-structure interaction (FSI) of Wedge Drop Slamming  
Lianxia Li, Mark Fenn, Maysam Mousaviraad, University of Wyoming, Christine Gilbert, Virginia Tech — Fluid-structure interaction (FSI) of flexible bodies through computational and experimental methods. Computational FSI capability is developed at University of Wyoming based on a two-way coupled approach. The flow is resolved by URANS CFD modeling and non-linear FEM equations are employed for structural dynamics. Slamming experiments are carried out at Virginia Tech for a 20 degree angle aluminum wedge with a bottom plate thickness of 3.175 mm and drop heights ranging from 0.9 to 38.1 cm. Measurements include time histories of vertical position, acceleration, pressure, and strain. Strain measurements are taken at single points using strain gauges as well as full-field measurements of all strain components and out-of-plane deflection using stereoscopic digital image correlation (S-DIC). Computational studies include validation and investigations of the physics involved in the interactions. Next step will extend to highly flexible structures where the two-way nonlinear interactions are more significant.

3:39PM A01.00004 How air deforms the free surface just before disk impact on a liquid bath  
Devaraj Van Der Meer, Utkarsh Jain, Anaïs Gautier, Detlef Lohe, University of Twente — When a flat disk impacts onto a liquid bath, a layer of air is trapped between the disk and the free surface, a phenomenon known as air cushioning. The air layer is pushed out at increasing speeds, causing the water surface to be lifted up towards the approaching disk. This qualitative observation is traditionally ascribed to Bernoulli suction occurring in the low-pressure region created by the large air velocities in the gap. Here, by means of a novel high-speed imaging technique that uses the free surface as a mirror, we quantitatively measure the time evolution of the free surface profile. The predicted elevation of the free surface below the disk is observed to be followed by an unanticipated depression just outside the disk’s edge. Although this depression starts growing at a later point in time, its magnitude eventually surpasses that of the elevation. We show that the results are inconsistent with Bernoulli suction and that instead, the deformation appears to be initiated by a Kelvin-Helmholtz instability occurring under the edge of the approaching disk.

3:52PM A01.00005 Passive Cavity Deflation after Water Entry  
Emma Fraley, Rafsan Rabb, Utah State University, Kelli Hendrickson, Massachusetts Institute of Technology, Tadd Truscott, Utah State University — Under specific impact conditions, objects form cavities when they enter a quiescent surface and persist for an extended time. The ability to quickly deflate or remove the cavity is important for naval, acoustic and marine applications. Herein, we propose a passive cavity deflation mechanism made of a hollow tube attached to a sphere with radial holes near the base, called the Kiara tube. We perform a series of experiments varying tube length, radial hole area and drop height to assess what factors influence cavity deflation and utilize high-speed cameras and image processing to quantify the cavity deflation. In general, tube lengths less than a critical length provide no deflation while larger tube lengths provide a consistent deflation rate. We will also discuss the effects of additional factors such as drop height, radial hole area, surface coatings, and forces as they relate to the cavity deflation rate.
The effect of bending stiffness on the impact of flexible plates on a water surface\textsuperscript{1}, AN WANG, KIT PAN WONG, MIAO YU, KENNETH T. KIGER, JAMES H. DUNCAN, University of Maryland, College Park, UNIVERSITY OF MARYLAND, COLLEGE PARK TEAM — The controlled oblique impact of a series of flexible/rigid rectangular plates (length 108 cm, width 41 cm, pitch angle 10\textdegree) on a quiescent water surface is studied experimentally. The flexible plates, which are made of 6061 aluminum, have various thicknesses while the rigid plate structure is made of two aluminum plates stiffened by a light-weight frame glued between them. The mounting structure allows each end of the plate to rotate around a transverse horizontal axis located slightly above the plate. For each plate, the motion trajectory and the impact speed are varied. The plate thickness and impact speed are chosen so that the impact time scale is on the same order of the wet natural period of the plate. The spray formation, the transient impact force, the moment about a horizontal transverse axis, the deflection along the plate’s center line and the impact pressure on the plate’s lower surface are measured with various techniques. For the same plate, it is found the maximum impact force/moment scale with the square of the component of the impact velocity normal to the undeformed plate. The temporal evolution of impact force and moment arm each have two distinct slopes. The relationship of this behavior to the plate’s deformation is explored.

Tuning the restitution coefficient of closed containers partially filled with water\textsuperscript{1}, PABLO GUTIERREZ, GUSTAVO CASTILLO, Universidad de O’Higgins, VICENTE SALINAS, Universidad Autónoma de Chile, FRANCISCO OLEA, LEONARDO GORDILLO, Universidad de Santiago — It is well known that when open containers partially filled with water fall, a strong jet emerges after they hit the ground (Milgram, JFM, 1969). Surprisingly Antkowiak et al. (JFM, 2007) showed that if the water surface of the flow remains perfectly flat during the fall, no jet forms at all. In this work, we show how the shape of the water surface just before the impact not only has an effect on the presence of the jet but also on the rebound of the overall system (container+water). We focus in closed containers and study the influence of the filling fraction, which has been shown to be a relevant ingredient in the bouncing of spherical containers filled with grains and liquid. Our observations suggest a different mechanism of why the flat surface prevents jet formation compared to the open container and the viscous sublayer is not the key ingredient in the jet formation. From the overall system energy point of view, the reflection coefficient is always higher than the reflection coefficients of the container and liquid interfaces taken separately. We hypothesize that the two interfaces act together to generate the final energy reflection coefficient.

A theory for the Pierson and Moskowitz spectrum\textsuperscript{1}, ANTHONY BONFILS, WOOSOK MOON, DHUBADITYA MITRA, JOHN WETTLAUFER\textsuperscript{2}, Nordic Institute for Theoretical Physics — The spectrum of surface gravity waves was measured in the sixties by Pierson and Moskowitz for a fully developed sea, however a theory explaining their observations has been lacking. In 1957, Miles proposed an instability mechanism for single mode growth involving the solution of the hydrodynamic equation with high growth at the critical level, which is the height at which the phase speed of the wave is equal to the wind speed. The turbulent wind is modeled by a logarithmic profile. We show that the introduction of a viscous sublayer does not affect the growth rate. Because there is a continuous spectrum of waves, we study the interaction between the different critical layers (the counterpart of wave-wave interactions) in the framework of the quasi-linear model of Janssen (1982). The natural small parameter in this system is the air/water density ratio, which introduces a scale separation in wind-wave generation. Whereas the evolution of gravity waves occurs on a short (fast) time scale, the energy transfer from the wind occurs on a long (slow) time scale. The feedback of growing surface waves on the wind profile occurs on an intermediate time scale. A decrease of its curvature leads to the saturation of the waves, which is the first step in the transition towards a fully developed sea.

\textsuperscript{1}Nordic Institute for Theoretical Physics — The fundamental knowledge of the airflow over the surface of the ocean is essential for evaluating air-sea fluxes. Despite recent numerical/theoretical advances, experimental data near the water interface have been difficult to obtain, especially for scales at which viscosity plays a role. Here, we present direct measurements of the velocity field in the turbulent airflow above wind waves for a range of 10-m wind speed varying from 2 to 17 m/s. Improvements in measuring techniques have allowed us to detect the viscous sublayer in the airflow near the interface and make direct measurements of the airside viscous stresses. In a phase-averaged sense, the viscous stress is highest on the upwind face of wave crest with its peak value close to the wave crest and its minimum about the middle of the leeward side of waves. At wind speeds of 2 m/s, corresponding to winds in which wind waves are first generated, the mean tangential stress represents more than 50\% of the wind stress. The contribution of the viscous stress to the total momentum flux decreases significantly with increasing wind speed. In low winds, we also observe the viscous stress generated by the wave motion in the airflow. To the best of our knowledge, these are the first measurements of airside, wave-induced viscous stresses.

\textsuperscript{1}This research was supported by the National Science Foundation (NSF) through grant numbers OCE-0748767, OCE-1458977, and OCE-1634051.

Wave- and shear-induced viscous stress over wind waves\textsuperscript{1}, KIANOOSH YOUSEFI, FABRICE VERON, School of Marine Science and Policy, University of Delaware, MARC BUCKLEY, Institute of Coastal Research, Helmholtz-Zentrum Geesthacht — Detailed knowledge of the airflow over the surface of the ocean is essential for evaluating air-sea fluxes. Despite recent numerical/theoretical advances, experimental data near the water interface have been difficult to obtain, especially for scales at which viscosity plays a role. Here, we present direct measurements of the velocity field in the turbulent airflow above wind waves for a range of 10-m wind speed varying from 2 to 17 m/s. Improvements in measuring techniques have allowed us to detect the viscous sublayer in the airflow near the interface and make direct measurements of the airside viscous stresses. In a phase-averaged sense, the viscous stress is highest on the upwind face of wave crest with its peak value close to the wave crest and its minimum about the middle of the leeward side of waves. At wind speeds of 2 m/s, corresponding to winds in which wind waves are first generated, the mean tangential stress represents more than 50\% of the wind stress. The contribution of the viscous stress to the total momentum flux decreases significantly with increasing wind speed. In low winds, we also observe the viscous stress generated by the wave motion in the airflow. To the best of our knowledge, these are the first measurements of airside, wave-induced viscous stresses.

Observations of water waves and wind-wave interactions in the Gulf of Aqaba (Eilat)\textsuperscript{1}, ALMOG SHANI-ZERBIB, RONI HILEL GOLDSHIMID, DAN LIBERZON, Technion - Israel Institute of Technology, T-FAIL TEAM — The Gulf of Aqaba (Eilat) at the northern tip of the Red Sea has a unique elongated rectangular shape, a stable diurnal cycle of wind regime and a steady climate. The resulted wind induced wave field is heavily influenced by the topography and bathymetry of the gulf area. These conditions make the gulf area an alluring location for wind-wave interactions research. Here, we report on a first ever high-resolution observations of the water wave regimes in the Gulf of Aqaba, conducted during two short campaigns in 2017 and 2019. These include wave field measurements using a directional wave gauge array accompanied by wind velocity field measurements at several heights. High resolution measurements of the wind flow turbulent characteristics were also conducted using the newly developed combo probe, a collocated ultrasonic and hot-wire anemometer, utilizing an in-situ Neural Network calibration procedure. We will report on the characteristics of the wind induced water wave fields and detail the wind-wave interaction dependence on the variations of the wind flow turbulence characteristics in terms of mean and fluctuating values. Empirical fits of the turbulent flow length scales vs. the wave field characteristics will also be presented.

3:39PM A02.00004 Influence of the free surface on the distribution of buoyant particles in wavy flow
- MICHELLE DIBENEDETTO, Woods Hole Oceanographic Institution.
- JEFFREY KOSEFF, NICHOLAS OUELLETTE, Stanford University — Using numerical and analytical techniques, we examine the effects of a varying free surface on the distribution of buoyant particles. We simulate particle dispersal scenarios under a progressive deep water wave train as well as under an idealized wave spectrum. This work implies that waves on the surface of the ocean can affect the instantaneous distribution of particles. These distribution effects can provide insight into how to interpret surface observations of particles, such as microplastics, using net trawls.

3:52PM A02.00005 Detection of breaking waves in single wave gauge records of surface elevation fluctuations
- DAN LIBERZON, ALEXANDRU VREME, SAGI KNOBLER, Technion - Israel Institute of Technology — We report the development of a new method for accurate detection of breaking water waves, which addresses the need for an accurate and cost-effective method that is independent of human decisions. The new detection method, which enables the detection of breakers using only surface elevation fluctuation data, is capable of detecting breakers from a single wave gauge. Furthermore, we develop a new methodology for research relating to water waves and wind-wave interactions. According to the proposed method, detection is based on the use of the Phase-Time Method (PTM) to identify breaking-associated patterns in the instantaneous frequency variations of surface elevation fluctuations. A wavelet-based pattern recognition algorithm is devised to detect such patterns and provide accurate detection of breakers in the examined records. Validation and performance tests, conducted using both laboratory and open sea data, including mechanically generated and wind-forced waves, are reported as well. These tests allowed derivation of a set of parameters assuring high detection accuracy rates. The method is shown to be capable of achieving a positive detection rate exceeding 90 percent.

4:05PM A02.00006 Predicting the breaking onset and strength of gravity water waves in arbitrary depth
- Morteza Derakhhti, APL-UW, Jim Kirby, UD, Jim Thompson, APL-UW, Stephan Grilli, URI, Mike Banner, UNSW — We introduce a robust and local parameterization to predict the breaking onset and breaking strength of 2-D and 3-D gravity water waves in arbitrary depth. We use a LES/VOF model to simulate nonlinear wave evolution, breaking onset and post-breaking behavior for representative cases of 2-D and 3-D focused wave packets, modulated wave trains, regular and irregular waves propagating over various bed topographies featuring deep water, intermediate depths, and the shallow surf zone. We also use a 2D potential flow solver using BEM to simulate nonlinear wave evolution, focusing on breaking onset behavior. The new parameterization relates the breaking strength to a breaking strength predictor $\Gamma$ defined as the normalized rate of change of $B = U/C$ following the wave crest (with $U$ the water velocity at the crest and $C$ the crest celerity). We show that the breaking onset criterion proposed by Barthelemy et al. (2018) in deep water is also effective in shallow water (i.e., when $B > B_{th} \sim 0.85$ then breaking is imminent). The new parameterization is local and can handle multiple breaking events in space and time. The implementation of the new parameterization is convenient and efficient in phase-resolving models such as Boussinesq and HOS models.

4:21PM A02.00007 Numerical simulation of nonlinear and dispersive wave breaking in arbitrary depth
- Morteza Derakhhti, APL-UW, Jim Kirby, UD, Jim Thompson, APL-UW, Stephan Grilli, URI, Mike Banner, UNSW — We introduce a robust and local parameterization to predict the breaking onset and breaking strength of 2-D and 3-D gravity water waves in arbitrary depth. We use a LES/VOF model to simulate nonlinear wave evolution, breaking onset and post-breaking behavior for representative cases of 2-D and 3-D focused wave packets, modulated wave trains, regular and irregular waves propagating over various bed topographies featuring deep water, intermediate depths, and the shallow surf zone. We also use a 2D potential flow solver using BEM to simulate nonlinear wave evolution, focusing on breaking onset behavior. The new parameterization relates the breaking strength to a breaking strength predictor $\Gamma$ defined as the normalized rate of change of $B = U/C$ following the wave crest (with $U$ the water velocity at the crest and $C$ the crest celerity). We show that the breaking onset criterion proposed by Barthelemy et al. (2018) in deep water is also effective in shallow water (i.e., when $B > B_{th} \sim 0.85$ then breaking is imminent). The new parameterization is local and can handle multiple breaking events in space and time. The implementation of the new parameterization is convenient and efficient in phase-resolving models such as Boussinesq and HOS models.

4:39PM A02.00008 Validation and performance tests of a new technique for the detection of breaking waves
- Shahin Ranjarzadeh, Department of Mechatronic and Mechanical Systems University of Sao Paulo Brazil, Renato Picelli, Polytechnic School University of Sao Paulo Brazil, Raghavendra Sivapuram, Structural Engineering, University of California, San Diego, Emilio Carlos Nelli Silva, Department of Mechatronic and Mechanical Systems University of Sao Paulo Brazil. — This work presents a coupled topology optimization methodology to predict the breaking onset in a fluid flow channel. The methodology proposed here aims to apply the Topology Optimization of Binary Structure (TOBS) method to the development of new methodologies for research relating to water waves and wind-wave interactions. According to the proposed method, detection is based on the use of the Phase-Time Method (PTM) to identify breaking-associated patterns in the instantaneous frequency variations of surface elevation fluctuations. A wavelet-based pattern recognition algorithm is devised to detect such patterns and provide accurate detection of breakers in the examined records. Validation and performance tests, conducted using both laboratory and open sea data, including mechanically generated and wind-forced waves, are reported as well. These tests allowed derivation of a set of parameters assuring high detection accuracy rates. The method is shown to be capable of achieving a positive detection rate exceeding 90 percent.

4:55PM A02.00009 Inertial effects on wind-driven mixing in the coastal ocean
- Alexei G. Zheligov, Fred K. Schmugge, Broomfield, CO, United States — Inertial effects are important for coastal ocean processes, but they are not always easy to study and quantify. In this work, we present results of a field study of wind-driven mixing in the coastal ocean near Long Beach, California. We use a combination of direct measurements of wind stress and wave energy, and modeling to simulate the effects of wind and waves on the mixing process.

5:15PM A02.00010 A computational framework for simulating the transport of fine sediments in estuarine and coastal environments
- Mohammad Bagheri, Entebbe, Uganda, United States — A computational framework for simulating the transport of fine sediments in estuarine and coastal environments is presented. This framework is based on the coupling of a 3D hydrodynamic model with a 3D transport model. The hydrodynamic model is based on the Reynolds-averaged Navier-Stokes equations, while the transport model is based on the advection-diffusion equation.

5:35PM A02.00011 Toward a better understanding of sediment transport in estuarine and coastal environments
- Mohammad Bagheri, Entebbe, Uganda, United States — This talk presents a new approach for simulating sediment transport in estuarine and coastal environments. The approach is based on a coupled hydrodynamic-transport model that is capable of simulating the complex processes involved in sediment transport, including advection, diffusion, and deposition.

5:55PM A02.00012 An Eulerian method for mixed soft and rigid body interactions in fluids
- Xiaolin Wang, Harvard University, Ken Kamrin, Massachusetts Institute of Technology, Chris Rycroft, Harvard University — Fluid-structure interaction problems are encountered in many engineering and biological applications. In this work, we present an Eulerian approach for fluid-structure interactions that is simple to implement and capable of simulating multi-body interactions. When the solid is rigid, a projection step is formulated as a composite linear system that simultaneously enforces the rigidity and incompressibility constraints. When the solid is soft, a reference map technique is applied to characterize the body deformation in an Eulerian framework. Several examples including single soft and rigid flags, multiple rigid bodies, and soft-rigid combinations will be presented, with potential applications to biological systems.

6:15PM A02.00013 A soft material arena meter
- Johan Sundin, Shervin Bagheri, KTH Mechanics, Royal Institute of Technology, Katherina Kokmanian, Matthew Fu, Marcus Multmark, Mechanical and Aerospace Engineering Department, Princeton University — Micro air vehicles (MAVs) often operate in wind speeds of the same magnitude as their own velocity. In order to navigate and control them efficiently, there is a need to estimate the wind speed. Because of their low weight, around 100 g, a wind speed sensor must be small and lightweight. The sensor must also be able to withstand impulses from impacts or wind gusts. Most conventional sensor concepts today are unable to fulfill these requirements. We suggest a new flow sensor concept, based on electrically conductive soft materials, denoted organic elastic filament velocimetry (OEFV). This technique estimates flow velocity by measuring the strain a polymer ribbon in the flow experiences. The polymer ribbon can withstand strains of the order of $\epsilon \sim 1$, making it extremely durable, in contrast to most conventional materials. The ribbon is manufactured in polydimethylsiloxane (PDMS) and made piezoresistive by adding a thin layer of silver nanowires, so that the resistance of the ribbon can be related to the flow velocity. The large aspect ratio of the ribbon (length to thickness) simplifies the description of the flow around it and amplifies the sensor output. A fairly simple model of the sensor behavior is constructed and compared to experimental data.

A feasibility study on the potential for employing piezoelectric cantilever beams as vortex flow sensors. AMIR DANESH-YAZDI, Rose-Hulman Institute of Technology, OLEG GOUSSHCHA, Manhattan College, YIANNIS ANDREOPoulos, City College of New York — The Train of Frozen Boxcars (TFB) model was previously developed to study the effective one-way coupling of the force due to the advection of a vortex or train of vortices over a stiff piezoelectric cantilever beam. The TFB approach involves the advection of several boxcars of different amplitudes, widths and separations as a model for the fluidic force acting on the beam. In this talk, we explore utilizing the TFB model as a way to deduce the force that acts on the piezoelectric beam due to the vortex. This study is aimed to predict vortex properties associated with vortex flow such as vortex circulation, diameter and separation between vortices. Preliminary results indicate that while the original TFB model can predict the properties of an individual vortex rather well, the model requires tweaks in order to better predict vortex properties when a train of vortices are involved.

Pendulum in a Flow: Case of a Balanced Pendulum. ARIANE GAYOUT, Laboratoire de Physique, ENS de Lyon, CNRS, France, ARMANn GYLFASON, School of Science and Engineering, Reykjavik University, Iceland, NICOLAS PLIHON, MICKAEL BOURGOIN, Laboratoire de Physique, ENS de Lyon, CNRS, France — Fluid-structure interactions are the basis of the complexity of Aerodynamics, enhancing resonance in structures and turbulence in flows. Even simple systems like a pendulum can become more complex, as a hysteretic bistability shows up for a range of flow velocities when the pendulum confronts a flow. This is predicted by a simple balance of weight and aerodynamical forces, but non stationary response can be seen through spontaneous transitions between both stable positions. This dynamic can also be observed when the weight of the pendulum. By analyzing trajectories in different phase spaces, we recover a stochastic measurement of the drag and lift coefficients. Moreover, the pendulum oscillates around the horizontal at a frequency that is linked to the evolution of the normal drag coefficient with the angular position of the pendulum. The instantaneous lift and drag coefficients inferred from the dynamical behavior of the pendulum seems to be governed by the dynamical vortex shedding phenomena, which we currently investigate experimentally.

Segregation modeling of binary suspensions. STANY GALLIER, MATHIEU PLAUD, ArianeGroup — This study proposes a continuum model able to describe particle segregation in bidisperse non-colloidal suspensions. It is based on the Morris-Boulay suspension balance model [Morris and Boulay, J. Rheol., 1999] which has been here extended to two classes of particles with different sizes. Doing so gives rise to new quantities (basically, normal or shear viscosity by particle class) that are not available experimentally. Indeed, only the overall suspension normal and shear viscosity are reported and it is not known how they split with respect to particle size class. We therefore consider particle-resolved Stokes simulations of binary suspensions to address this point. Parametric simulations are conducted for different size ratio, total volume fraction and large/small fraction ratio. We show that both shear and normal viscosities are approximately proportional to volume fraction ratio. This allows to provide a simple closure for the model. It is then incorporated in a flow solver and successfully compared to available experiments of segregation in channel flows.

Simulating cross stream migration of hard spheres in a dilute suspension. NILANKA I. K. EKANAYAKE, JOSEPH D. BERRY, ANTHONY D. STICKLAND, DAVID E. DUNSTAN, The University of Melbourne, STEVEN K. DOWER, INEKE L. MUIR, CSL Limited, DALTON J. E. HARVIE, The University of Melbourne — In flowing suspensions, hydrodynamic forces can move particles across the streamlines and cluster at certain radial positions within a pipe. In the biological flow context, this cross-stream migration is widely used in cell sorting microfluidic applications to separate diseased cells based on size and other physical characteristics. This study employs a multi-fluid model to predict the solid concentration profiles of a mono-disperse suspension of hard spheres flowing at low particle Reynolds numbers. The lateral migration is modelled using wall-shear and shear rate gradient hydrodynamic lift forces and inter-particle hydrodynamic collision forces. Brownian and shear induced diffusion forces are modelled as functions of solid concentration gradients and shear rate gradients. The effect of bulk concentration on solid distribution is examined and compared against experimental data. At highly dilute conditions particles accumulate at 0.6 radius away from the centerline exhibiting the “tabular pinch” effect caused by lift forces. With increasing bulk concentration, particles gradually move towards the centerline due to diffusion forces. This study demonstrates that the bulk concentration has a significant impact in determining solid distribution profiles.
3:26PM A04.00003 Lubrication Corrections for Brownian Suspensions Above a Wall1
   BRENNAN SPRINKLE, ALEKSANDAR DONEV, YIXIANG LUO, Courant Institute of Mathematical Sciences — Lubrication effects play an
   important role in the dynamics of dense suspensions of passive or active microscale particles. In order to quantitatively measure bulk properties
   in these types of suspensions, the near-field lubrication flows must be accurately resolved. We present an efficient numerical method to simulate
dense Brownian suspensions of many particles above a bottom wall. Our method includes lubrication effects while maintaining a computational
complexity which scales linearly in the number of particles. Examples to demonstrate the effectiveness of our method include: the sedimentation
of particles over an inclined plane, as well as collective motion in a suspension of magnetic ‘rollers’.
1DMR-1420073, RTG/DMS-1646339

3:39PM A04.00004 Modeling and Stokesian-Dynamics Simulations of Friction in Colloidal Suspensions1, GERALD WANG, MIT Chemical Engineering; CMU Civil and Environmental Engineering, JAMES SWAN, MIT Chemical Engineering — As the gap between particles in a suspension approaches zero, inter-particle frictional forces can become
non-negligible. These forces may strongly influence structure and transport in systems with a significant number of particle-particle contacts,
as such as sticky colloidal suspensions. Understanding the influence of microscopic frictional contacts on macroscopic suspension properties is vital
for modeling many rheological phenomena, including discontinuous shear thickening. In this talk, we present computational and theoretical work
exploring the role of friction in colloidal suspensions, in which friction is treated as a hydrodynamic resistance to sliding between particles near
contact. Our Stokesian-Dynamics simulations demonstrate that the frictional suppression of both the translational and rotational diffusivities
can be related to the friction coefficient using a simple power-law scaling. To explain this result, we develop a spectral model that quantifies
the impact of friction on the hydrodynamic resistance tensor. We then show that a mathematical model of the suspension as a graph, which
tracks connections between neighboring particles, can be used to explain the observed dynamics. We also discuss experimental results.

3:52PM A04.00005 Particle migration of colloidal and Brownian suspensions in both Poiseuille and circular Couette flow1, CHANGWOO KANG, PARISA MIRBOD, University of Illinois at Chicago — The flow of neutrally buoyant and hard-sphere colloidal particles concentrated in a Newtonian viscous fluid is examined by direct numerical
simulations (DNS) at various bulk particle volume fraction (0.1 ≤ φp ≤ 0.5) and Peclet number (10−2 ≤ Pe≤103). We use the diffusive flux
model (DFM) to describe the behavior of suspensions and employ the viscosity introduced by de Kruijf et al. [J. Chem. Phys. 1985] which
is given as a function of shear rate and volume fraction. First, we consider pressure-driven flow of colloidal particles in a channel. For low
Pe number the concentration profile flattens, as Pe grows the influence of Brownian motion diminishes and the distribution of concentration
reaches the profile of non-colloidal suspensions flow. Also, as Brownian motion becomes dominant, the volume flow rate decreases steadily. We
then study a circular Couette flow of colloidal suspensions where the inner cylinder rotates with a constant angular velocity and the outer one is
fixed. The concentration profile flattens out and the local shear rate decays with the reduction of Pe number. The torque acting on the outer
inlet cylinder builds up due to colloidal suspensions.

4:05PM A04.00006 Graphene nanoplatelets attain a stable orientation in a shear flow: an investigation on the role of Brownian fluctuations1, CATHERINE KAMAL, SIMON GRAVELLE, LORENZO BOTTO, Queen Mary University of London — We study theoretically the rotational dynamics of a rigid graphene nanoplatelet
suspended in a simple shear flow. We have recently shown that in the infinite Peclet number limit a rigid platelet presenting the interfacial
hydrodynamic slip properties of graphene does not follow the periodic rotations predicted by Jefferys theory, but rather aligns itself at a small
inclination angle α with respect to the flow. This unexpected result is due to the low tangential friction at the graphene-solvent surface (the slip
lengths for many 2D materials/solvent combinations can amount to several tens of nanometers). By analyzing the Fokker-Plank equation for
the orientation distribution function for decreasing Peclet numbers, we show that the platelet fluctuates about α until a slip length dependent
critical Peclet number is reached. Below this value, Brownian forces are large enough to produce full rotations, bringing the particle outside of
a hydrodynamic potential well. In the stable region, the effective viscosity of a dilute suspension of graphene platelets is predicted to drop by
at least a factor of 2 for typical slip length values.

4:18PM A04.00007 Shear-induced exfoliation of graphite nanoplatelets into graphene: insights from non-equilibrium molecular dynamics1, SIMON GRAVELLE2, CATHERINE KAMAL, LORENZO BOTTO3, School of Engineering and Materials Science, Queen Mary University of London, E1 4NS, London, UK — Graphite nanoplatelets suspended in a shear flow can be exfoliated into single-layer or few-layers graphene. Such liquid-phase exfoliation
method is a promising technique for the production of graphene on large scales, but the micro and nanoscale fluid-structure processes controlling
exfoliation are not understood. Here we use molecular dynamics simulations of a defect-free graphite nanoplatelet suspended in a shear flow to
caracterise the exfoliation dynamics and measure the critical shear rate above which exfoliation occurs, comparing the effect of using different
solvents (water and NMP). The measured critical shear rates are compared with a simple theoretical model due to Chen et al. (Chem. Commun.,
48, (2012) 3703-3705) based on a balance between the work done by viscous shearing forces and the change in interfacial energies upon layer
sliding. We found it difficult to reconcile the molecular dynamics results with the model. The results obtained so far highlight the importance of
hydrodynamic slip at the liquid-graphene interface, and the effect of graphene edges on hydrodynamics and interfacial mechanics. Both effects
are incompletely included in the model.

3:00PM A05.00001 Normal shock wave attenuation during propagation in straight and branching ducts with grooves. SEYED MEHDI MORTAZAWY, Embry Riddle Aeronautical University, KOSTAS KONTIS, School of Engineering, University of Glasgow, JOHN EKATERINARIS, Embry Riddle Aeronautical University — Experimental investigations and numerical simulations of normal shock waves of different strengths propagating inside ducts with roughness are presented. The roughness is added in the form of grooves. Straight and branching ducts are considered in order to better explore the mechanisms causing attenuation of the shock and the physics behind the evolution of the complex wave patterns resulting from diffraction and reflection of the primary moving shock. A well-established finite volume numerical method is used and further validated for several test cases relevant to this study. The computed results are compared with experimental measurements in ducts with grooves. Good agreement between high-resolution simulations and the experiment is obtained for the shock speeds and complex wave patterns created by the grooves. High frequency response time histories of pressure at various locations were recorded in the experiments. The recorded pressure histories and shock strengths were found in fair agreement with the two-dimensional simulation results as long as the shock stays in the duct. Overall, the physics of the interactions of the moving shock, and the diffracted and reflected waves with the grooves are adequately captured in the high-resolution simulations.

3:13PM A05.00002 Combating shock waves: A study of shock wave cancellation mechanisms within linear turbine blade cascades. JORGE NUNEZ, VERONICA ELIASSON, UCSD — Prior research has established that unsteady shock wave interactions on turbine blades negatively impact the fatigue life and performance of gas turbines. Current technology in gas turbines mitigates negative effects on turbine blades by way of cooling mechanisms. However, recent inventions seek to eliminate the adverse influence that unsteady shock wave interactions have on turbine blades by cancelling incident shock waves in gas turbines. The goal of this study is to ascertain the efficacy of shock cancellation mechanisms in gas turbines at preventing incident shock waves from reflecting off the turbine blades. A study of shock wave cancellation in linear turbine blade cascades has been performed to analyze the performance of shock wave cancelling mechanisms. CFD simulations are compared to shock tube experiments featuring high-speed schlieren photography and pressure measurements of unsteady shock wave impacts on linear turbine blade cascades. Different shock wave cancelling designs has been investigated and the benefits and drawbacks of the chosen designs will be discussed.

3:26PM A05.00003 Scaling of compressible turbulent mixing. EUNHYE AN, ERIC JOHNSEN, University of Michigan — The decay of homogeneous, isotropic turbulence is well understood based on Kolmogorov theory in the incompressible limit. However, the roles of compressibility and inhomogeneities on the turbulence phenomenology are less well known. For this purpose, we conduct direct numerical simulation (DNS) to investigate the behavior of turbulent mixing, in which homogeneous isotropic turbulence regions of different intensities are juxtaposed. We investigate the scaling of the decay of turbulent kinetic energy (TKE) for this compressible, inhomogeneous flow. By considering the turbulent energy balance equation, we determine scaling coefficients predicting the observed behavior by accounting for dilatation. This scaling is verified by the DNS results of turbulent mixing as well as turbulent/non-turbulent interfaces.

3:39PM A05.00004 Direct Simulation of Fluid-Structure Interaction in a Hypersonic Compression Ramp Flow. BRYSON SULLIVAN, University of Illinois at Urbana-Champaign, THOMAS WHALEN, STUART LAURRENCE, University of Maryland, DANIEL BODONY, University of Illinois at Urbana-Champaign — Sustained hypersonic flight presents an enduring challenge to aircraft design and control. An extreme aerothermal environment acting on thin, multi-functional structures can yield significant fluid-thermal-structural interaction (FTSI) in control surfaces and/or a complete vehicle. While computationally efficient, the accuracy of reduced-order aerodynamic models can be compromised by local regions of subsonic/separated flow, highlighting the need for high-fidelity numerical simulations. The present talk outlines recent time-accurate FTSI simulations of a viscous flow at $M_{∞} = 6.0$ over a 35° compression ramp with an embedded compliant panel. Reduced-order models are compared directly to FTSI simulation data, and a simple modification is proposed which can improve the accuracy of shock-expansion/local piston theory predictions. A reduction in surface heat flux is observed for most compliant cases, while traditional heat transfer analogies were found to be reliable only for the rigid case. Oscillation of the reattachment point was found to synchronize with the motion of the compliant panel for large-amplitude vibrations.

3:52PM A05.00005 Simulation and Global Stability Analysis of a 35° compression ramp in a uniform Mach 6 flow. FABIAN DETTENRIEDER, DANIEL BODONY, University of Illinois at Urbana-Champaign — Aerothermal and structural loads of flows relevant to hypersonic vehicles pose a multi-disciplinary design problem. Of particular interest is the fluid-structure interaction associated with a deflected control surface at sufficiently high Mach number such that the compression shock sits on the control surface downstream of the corner, leading to large localized pressure and thermal loads. As a baseline for subsequent compliant analyses, we investigate the Mach 6 flow past a rigid 35° degree compression ramp attached to a finite-length flat plate, which together model the control surface geometry, by means of direct numerical simulation (DNS). The three-dimensional DNS results include the boundary layer development from the plate’s leading edge, through transition, and ultimate transition to turbulence. The unsteadiness of the separation bubble and observed ejection of mass and shocklets from the separation bubble are quantified and compared to experimental data. We use global stability analyses of the time-averaged flow to discuss the observed unsteadiness in terms of global modes.

theory1, Maryam Akram, Venkat Ramani, University of Michigan, Ann Arbor — Resolving all dynamical scales in reacting

3:26PM A06.00003 Numerical and Experimental Study of Piloted Liquid Spray
Flames, Dorrin Jarrahbashi, Yejun Wang, Salar Taghizadeh, Waruna Kulatilaka, Texas A&M University, Texas A&M UNIVERSITY TEAM — Liquid-fuel spray flames are the primary mode of energy conversion in many high-power-density practical combustion devices. A modified, flat-flame McKenna burner fitted with a direct-injection high-efficiency nebulizer is used to produce piloted liquid-methanol spray flames. A 3D computational model is developed which comprised of compressible continuous gas phase using URANS in conjunction with two-way coupled Eulerian-Lagrangian spray modeling approach along with a partially-stirred reactor combustion model. Model predictions of Hydroxyl (OH) and carbon monoxide (CO) in the radial and axial directions at different flame locations are compared with laser-based imaging measurements. OH profiles are obtained using nanosecond planar laser-induced fluorescence (PLIF) for characterizing the reaction zone and temperature, while 2D images of CO are obtained via two-photon laser-induced fluorescence (TPLIF) using femtosecond-duration laser pulses. The computational model predicts the general trends of OH, temperature and CO profiles well at certain heights above the burner surface. The sensitivity of the model to the droplet size distribution, pilot flame temperature, and the co-flow temperature are discussed.
3:39PM A06.00004 A novel deep learning framework for efficient parameterization of high-dimensional flamelet manifolds. OPEOLUWA OWOYELE, PRITHWISH KUNDU, PINAKI PAL, Argonne National Laboratory — Tabulated flamelet models are limited by the curse of dimensionality, wherein the computational memory required to store multidimensional flamelet lookup tables grows exponentially as the number of independent variables increases. In addition, it requires a vast increase in code complexity to perform interpolations in higher dimensions. One promising technique is to train an ANN \textit{apriori} based on the flamelet table, and use the trained model during run-time to obtain the species mass fractions as functions of the independent variables. Results from a previous study showed that training accuracy and inference speed can be improved if the multidimensional data set is bifurcated and separate ANNs are used for different regions. In this work, an \textit{apriori} study is performed using a physically meaningful divide-and-conquer approach, where an ensemble of deep neural networks is trained to represent the relevant physics in different regions of the flamelet manifold, as supervised by a gating network. The method is applied to 4-dimensional and 5-dimensional flamelet tables representing spray combustion in a constant volume chamber (ECN spray A) and a compression-ignition engine, respectively. The technique is demonstrated to result in a further decrease in the computational cost for a given accuracy. Moreover, the physical meaning of the obtained partitions is also discussed.

3:52PM A06.00005 Mass transfer coupled to chemical reaction through a random array of fixed porous particles. ERIC CLIMENT, Institut de Mecanique des Fluides de Toulouse, MOSTAFA SULAIMAN, ABDELKADER HAMMOUTI, IFP-EN, ANTHONY WACHS, University of British Columbia, UNIV. OF BRITISH COLUMBIA COLLABORATION — We have studied by means of numerical simulations the effect of a first order irreversible chemical reaction on mass transfer for two-phase flow systems in which the continuous phase is a fluid and the dispersed phase consists in catalyst spherical particles. The reactive solute is transported by the fluid flow and penetrates through the particle surface by diffusion. The chemical reaction takes place within the bulk of the particle. We handle the problem by coupling mass balance equations for internal-external transfers through the particle surface. We propose a model to predict mass transfer coefficient accounting for the external convection-diffusion along with internal diffusion-reaction. For the simulation of multi-particle systems, we have implemented a Sharp Interface Method to handle strong concentration gradients in DLM/FD framework. We validated the method thoroughly thanks to comparison with analytical solutions in case of diffusion, diffusion-reaction and by comparison with previously established correlations for convection-diffusion mass transfer. Finally, we study the configuration of a fixed bed of catalyst particles. We introduce a model that accounts for the solid volume fraction, in addition to the aforementioned effects and compare to numerical simulations.

4:05PM A06.00006 Quasi-static Eulerian framework for thermomechanical heterogeneous solid propellant simulations. TADBHAGYA KUMAR, THOMAS JACKSON, University of Florida — Heterogeneous solid propellants find prevalent use in space missions and thus understanding physics that influences their performance becomes critical to design. Numerical simulation of propellant combustion is complex owing to multiphysics nature with a burning surface that propagates through pyrolysis law. Of interest is to predict the thermomechanical stresses and strains that might lead to damage/failure of the constituent materials of the propellant under combustion. In this work, a Eulerian framework for thermomechanical simulations of propellant combustion using the hypoelastic equation is presented. A quasi-static projection method is motivated through scaling analysis and a finite element based weak form is employed to deal with material moduli differences. The simulations are carried out in two-dimensional propellant packs and results are presented for the temperature, stress, and their effect on propellant burn rate.

4:18PM A06.00007 A Novel Experiment-Based Framework for Turbulent Combustion Modeling. RISHIKESH RANADE, TAREK ECHEKKI, North Carolina State University — A novel framework for turbulent combustion modeling is presented. The framework is based on the construction of conditional means and joint scalar PDFs from multiscalar measurements in flames based on the parameterization of composition space using principal component analysis (PCA). The resulting principal components (PCs) act as both conditioning and transported variables. Their chemical source terms are constructed starting from instantaneous temperature and species measurements using a variant of the pairwise mixing stirred reactor (PMSR) approach. A multi-dimensional kernel density estimation (KDE) approach is used to construct the joint PDFs in PC space. The PDFs’ dimension corresponds to the number of retained PC’s and the composition conditional means provide measures of the unconditional means for the closure terms: the mean PCs chemical source terms and the density. The framework is demonstrated a priori and posteriori using data from different flames.

Saturday, November 23, 2019 3:00PM - 4:31PM — Session A07 Aerodynamics: Airfoil

3:00PM A07.00001 Data-driven analysis of vortex dynamics around a sinusoaidally pitching airfoil. KARTHIK MENON, RAJAT MITTAL, Johns Hopkins University — Data-driven methods to analyze fluid flows have been recently gaining popularity in many subdomains of fluid dynamics. This has been primarily driven by our improved ability to generate large, high-quality data sets, and efforts to extract patterns from large amounts of data in an efficient manner. This talk will describe our work to understand the dynamics of aeroelastic flutter from one such data set consisting of over 500 simulations of a sinusoaidally pitching airfoil under different conditions. In particular, the focus will be on the analysis of the vortex dynamics close to the surface of the airfoil as well as in the wake, which is instrumental in driving flutter. We describe a new dynamic mode decomposition (DMD) formulation that allows us to decompose the flow in the vicinity of the moving airfoil and also discuss data-driven clustering methods to identify distinct vortex patterns in this complex flow.

3:13PM A07.00002 Fluttering, twisting and orbital motions of wall-mounted flexible plates. YAQING JIN, The University of Texas at Dallas, SHYUAN CHENG, LEONARDO P. CHAMORRO, University of Illinois at Urbana-Champaign — The dynamics of wall-mounted flexible plates under inclined flows was studied for a variety of Cauchy numbers using theoretical arguments and laboratory experiments. Particle tracking velocimetry and a high-resolution force sensor were used to characterize the plate dynamics and aerodynamic force. Results show three distinctive modes of tip oscillations, which are modulated by the structure dynamics and flow. The first mode is characterized by small-amplitude motions occurring by small Cauchy number. Past this condition, the motions are dominated by unsteady twisting patterns. The onset of this mode is characterized by a sharp increase of the force fluctuation intensity. At sufficiently high Cauchy number and flow inclination, the plate may undergo a third mode dominated by large-scale tip orbits about the mean bending. We propose a formulation to estimate the critical Cauchy number as a function of inclination angle, which agrees well with experiments.
3:26PM A07.00003 On the multiscale oscillations of a hinged plate under stratified turbulence1, SHYUAN CHENG, Department of Mechanical Science and Engineering, University of Illinois, Urbana, IL, 61801, YAQING JIN, Department of Mechanical Engineering, The University of Texas, Richardson, TX, 75080, LEONARDO P. CHAMORRO, Department of Mechanical Science and Engineering, University of Illinois, Urbana, IL, 61801 — Wind-tunnel experiments were conducted to quantify the unsteady motions of a rigid plate under stratified turbulence containing spatially-varied, energetic vortices. The structure was able to oscillate around a vertical axis located at a quarter chord length from the leading edge. Vertically-oriented, von-Karman vortices that varied in frequency and strength along the vertical span of the plate were imposed using a variety of tapered cylinders. Telemetry and hotwire anemometry were used to characterize the motions of the plate, and wake at selected locations. Results show that the plate oscillation is dominated by two distinct modes. One of them, f_p, corresponds to the mean flow-induced oscillation frequency; whereas the other, f_v, is related to the vortex shedding cells from the non-uniform cylinders. These frequencies exhibited distinct trends with the distance from the cylinders, and the distribution of the coherent motions, which were determined by the tapered ratio of the cylinders. A simple model is proposed to estimate f_v.

3:39PM A07.00004 Flutter-Enhanced Mixing: Flow-Induced Flutter of Flexible Membranes in Small Scale Mixers2, AARON RIPS, NASA/Jacobs Space Exploration Group, RAJAT MITTAL, Johns Hopkins University — Flow-induced flutter of flexible membranes in small scale mixers is explored. Fully-coupled fluid-structure-scale interaction (FSI) simulations are used to examine the mixing enhancement in duct-style small scale mixers due to fluttering flags and the sensitivity of the dynamics and the mixing performance to Reynolds number is examined. The fluid and structural dynamics are explored and the resultant mixing enhancement is characterized according to existing performance measures as well as two new analysis techniques. A new performance measure called the Equivalent Mixing Length is developed to examine the connection between increased mixing performance and the corresponding increase in pressure loss which can serve as a measure of performance efficiency of flutter mixers or of any micromixer design. Additionally, a technique is developed to extract an estimate of the interface path length in the flow so as to characterize the impact of increased convection due to the presence of the flutter mixer. Through these measures it is shown that flutter mixers can significantly improve the mixing performance of a small scale mixer over a very small duct length by way of generating vortical structures even at low Reynolds numbers which leads to complex stretching and folding of the interface in the mixer.

3:52PM A07.00005 Nonlinear Stability Characteristics of an Elastically Mounted Pitching Wing1, YUANHANG ZHU, YUNXING SU, KENNETH BREUER, Brown University — We study the nonlinear stability boundaries of an elastically mounted pitching wing in a water flume, with the wing structural dynamics (inertia I, stiffness k, damping b) simulated using a cyber-physical system. We fix b to be small and systematically vary k at different I to test for the onset and extinction of self-excited oscillations. We find that as k increases, the system bifurcates from a fixed point towards small-amplitude limit cycle oscillations via a subcritical bifurcation, which features hysteretic bistability and an abrupt amplitude jump at the bifurcation. At this I, the wing pitching frequency f_p locks onto its structural frequency f_s, indicating dominating structural force. Force and PIV measurements reveal the emergence of a secondary leading edge vortex (LEV) after the shedding of the primary LEV. As I decreases, the width of the bistability region shrinks. When I is sufficiently low, the pitching amplitude changes gradually with k without hysteresis, revealing a supercritical bifurcation. At this I, f_s is relatively constant and lower than f_p, indicating dominating fluid force. The secondary LEV is not present. We also report the effect of sweep angles on the stability boundaries.

4:05PM A07.00006 Periodic Loading of a Mach 4 Boundary Layer over a Compliant Surface by an Oscillating Shock Generator1, MALLORY NEET2, JOANNA AUSTIN3, California Institute of Technology — A significant challenge in designing hypersonic vehicles is developing predictive models for aerodynamic loads associated with turbulent boundary layers and shock boundary layer interactions on compliant surfaces. Shock-boundary layer interactions on high-speed vehicles can lead to pressure fluctuations which can couple to structural modes and lead to premature high-cycle fatigue and ultimately component failure. In collaboration with simulations, some experimental studies can give insight into the degree of fluid-structure coupling under prescribed loading conditions. In this presentation, the flow response over a 0.2 mm thick compliant steel panel under dynamic loading from an oscillating shock generator is investigated in the Caltech Mach 4 Ludwieg tube. Euler simulations were performed to design the geometry and location of the shock generator, predict the amplitude of the oscillation required to drive the pressure wave across the compliant surface, and to calculate the pressure rise on the compliant surface. The flow response is characterized using fast-acting pressure transducers, high-speed schlieren images, and porous fast-response pressure sensitive paint and the panel response using laser doppler vibrometry. 

4:18PM A07.00007 Anemometry from visual observations of fluid structure interactions1, JENNIFER L. CARDONA, MICHAEL F. HOWLAND, JOHN O. DABIRI, Stanford University — Visual observations of objects interacting with the wind contain information about local wind conditions such as wind speed. These visual encodings can potentially be leveraged to measure wind speeds using videos of pre-existing objects in an environment (e.g. flapping flags or swaying trees). We propose a data driven approach that leverages deep learning methods to predict wind speeds given video recordings of fluid structure interactions. Video clips of flags and trees moving due to naturally occurring wind are used to estimate wind speeds through the application of a convolutional neural network followed by a recurrent neural network. Physical parameters of the observed objects are used to aid in understanding limitations of model performance.

Saturday, November 23, 2019 3:00PM - 4:31PM — Session A08 Surface Tension I 212 - Hassan Masoud, Michigan Tech

3:00PM A08.00001 Rifts in Rafts1, KHA-I TO, DANIEL HXNER, VINCENZO VITELLI, SIDNEY NAGEL, University of Chicago — Two-dimensional particle rafts are single-layers of aggregated sub-millimeter polydisperse particles floating at an air-fluid interface. The material failure of such rafts under an applied extensional load has a morphology that appears to be distinct from other known fracture modes. At higher extensional shear rates, numerous small-scale cracks are distributed diffusively throughout the entire system; at low strain rates, the distance between adjacent cracks increases. The characteristics of this distributed failure also depend on the surface tension and viscosity of the underlying fluid. To decrease the influence of secondary flows, we perform experiments by changing the liquid level in the tanks with inclined walls so that we are able to increase the area accessible to the rafts as the liquid height changes. This results in an expansion in quasi-1D (with and without boundaries) and isotropic 2-D expansion in the linear and cylindrical geometries respectively. We simulate this behavior with a model based on weak interparticle forces coupled to an expanding underlying metric.
3:13PM A08.00002 Morphology Regulation of Liquid-Gas Interface on Bioinspired Super-Repellent Surface. YAOLEI XIANG, PENCYU LV, HUILING DUAN, Department of Mechanics and Engineering Science, College of Engineering, Peking University, Beijing 100871, P. R. China — Bioinspired underwater super-repellent surfaces have many excellent properties, which attribute to the air mattress trapped on the surface. However, instability and collapse of the underwater slippery air mattress hinder its applications, after which the air mattress is difficult to recover. Here, we find that the unique hierarchical structures on the leaf surface of a famous invasive floating fern, Salvinia, have the capacity to replace the impregnated water with air and entirely recover the air mattress. We reveal the underlying mechanisms of the recovery process. The interconnected wedge-shaped grooves on the bottom are key to the recovery, which spontaneously transport the replenished air to the entire surface governed by a gas wicking effect. Moreover, inspired by the nature of Salvinia, we fabricated artificial Salvinia surfaces using three-dimensional printing technology, which successfully achieve a complete recovery of a continuous air mattress to exactly imitate the super-inflatable capability of Salvinia leaves.

3:26PM A08.00003 Collapse of a Compressed Granular Raft1. BEN DRUECKE, XIANG CHENG, SUNGYON LEE, University of Minnesota — Rigid, passive particles at the interface between two fluids provide a compression-resistant interface, thus opposing area-minimizing interfacial energy and providing the stabilizing effect characteristic of Pickering emulsions. We experimentally and analytically investigate the behavior of a flat particle raft under isotropic compression. A granular raft of glass spheres with diameter in the range of 0.1 to 2 mm is formed on a fluid-fluid interface within a conical funnel. Axissymmetric compression of the raft is imposed by draining fluid from the funnel. Two distinct modes of raft deformation and collapse are observed, depending on particle size and the two fluids forming the interface. In the first mode, individual particles fall from the raft in seemingly uncorrelated events. In the second, the raft collectively deforms and creases, akin to a Rayleigh-Taylor instability. We analytically and experimentally examine the two modes of raft collapse as a function of particle size, fluid densities and surface energies.

3:39PM A08.00004 Deformation of quasi-two-dimensional drops traveling in a microchannel.1. PABLO MARDONES MUÑOZ, MARÍA LUISA CORDERO GARAYAR, Universidad de Chile — When water and oil are injected into a shallow channel, water droplets form in a quasi-two-dimensional geometry. In an equilibrium situation the water-oil interface of the drops adopts a circumferential shape of radius R to minimize the energy. However, when a pressure gradient puts the system out of equilibrium, the shape of the droplets is modified to respond to the strains on their edge.

To characterize the deformation of the drops, we have measured the interface shape and decomposed it into Fourier modes. We focus on the evolution of the drop deformation, since their formation until they reach their equilibrium shape. By varying the experimental conditions, we study drop shape and its evolution as a function of the capillary, Ca, number and the confinement of the drops in the shallow channel, d. We have found a scale law in which the steady-state root mean square deformation of the drops is proportional to the confinement d to the fourth power.

3:52PM A08.00005 ABSTRACT WITHDRAWN –

4:05PM A08.00006 Forward, halted, and reverse motion of an active particle atop a finite liquid layer1. SAEED JAFARI KANG, Michigan Tech, JONATHAN ROTHSTEIN, University of Massachusetts Amherst, HASSAN MASOUD, Michigan Tech — We examine the mobility of a chemically active particle straddling the interface between a liquid layer of finite depth and a semi-infinite layer of gas. A surface-active agent is released asymmetrically from the particle that locally lowers the liquid surface tension. It is commonly presumed that the uneven distribution of surface tension and the associated Marangoni flow lead to the propulsion of the active particle opposite to the release direction, where the surface tension is higher. This is considered forward motion. However, our recent theoretical analysis (in the limits of negligible inertia and diffusion-dominated transport of the active agent) has shown that this trend may be reversed for certain particle shapes and shallow enough liquid layers. Advancing beyond the Stokes regime, here, we numerically study the Marangoni-driven motion of oblate spheroidal particles for a wide range of release rates and subject to various degrees of confinement, represented by the thickness of the liquid film. We show that this trend may be reversed for certain particle shapes and shallow enough liquid layers. Advancing beyond the Stokes regime, here, we numerically study the Marangoni-driven motion of oblate spheroidal particles for a wide range of release rates and subject to various degrees of confinement, represented by the thickness of the liquid film. We show that this trend may be reversed for certain particle shapes and shallow enough liquid layers.

4:18PM A08.00007 Flow through a Catenoid: The Fluid Tube1. MACKENZIE DUCE, California Polytechnic State University at San Luis Obispo, AARON BROWN, DANIEL HARRIS, Brown University — Minimal surfaces have been studied for centuries by mathematicians, and can be readily realized using fluid films such as a film of soapy water. In particular, two rings are known to be connected by a catenoid-shaped film, however, beyond a critical ring spacing the catenoid solution fails to exist and the structure collapses. In this work, we experimentally investigate a variation of this classic problem by introducing steady flow through the catenoid structure formed by an oil film in water. We demonstrate that the flow robustly stabilizes a thin tube-like structure, with lengths well beyond the critical spacing anticipated without flow. We characterize the shape, length, and stability of this novel “fluid tube structure as a function of the flow rate, ring diameter, and ring shape.

1We acknowledge the financial support of the Cal Poly Physics Department

Saturday, November 23, 2019 3:00PM - 4:31PM – Session A09 FSI: Sheets / Membranes 213 - Shai B. Elbaz, Technion - Israel Institute of Technology
3:00PM A09.00001 Experimental and computational studies of flexible membrane aerodynamics. RODRIGO PADILLA, CONAL THIE, VIBHAV DURGESH, TAO XING, University of Idaho — Fluid-structure interaction (FSI) problems involve the interaction of flexible bodies or membranes like flexible airfoils, parachutes, and sails, with fluid flows. A detailed understanding of the flow dynamics and structure behavior is critical to resolving FSI problems. The objective of the current study is to quantify the impact of critical dimensionless parameters (Re, aspect ratio, dimensionless rigidity) on flow field, vortex shedding, surface pressure distribution, and membrane response, for a canonical rectangular flexible membrane with varying aspect ratios. A collaborative experimental and computational investigation was performed, and the membrane was fabricated using 3D printers. The experiments for this investigation were performed in a subsonic wind tunnel facility and the flow field was measured using Particle Image Velocimetry (PIV). The Reynolds number ranged from 50,000 to 200,000. Analytical and computational fluid dynamics (CFD) studies were performed. The results show that the interaction between the front and rear segments is the dominant mechanism for instability for various discrete locations of clamping. The results yield the maximal stable speed as a function of elastic damping, fluid density and location of clamping. The results show that the interaction between the front and rear segments is the dominant mechanism for instability for various discrete locations of clamping.

3:13PM A09.00002 ABSTRACT WITHDRAWN —

3:26PM A09.00003 Dynamics and instabilities of an arbitrarily clamped elastic sheet in potential flow. SHAI B. ELBAZ, NETHANEL CHEN, AMIR D. GAT, Technion - Israel Institute of Technology — Shape-morphing airfoils have attracted much attention in recent years. They offer substantial drag reduction by comparison to conventional airfoils and a premise of superior aerodynamic performance. In the current work, we model a shape-morphing airfoil as two, rear and front, Euler-Bernoulli beams connected to a rigid support. The setup is contained within a uniform potential flow field and the aerodynamic loads are modeled by thin airfoil theory. The aim is to study the dynamics and stability of such soft shape-morphing configurations and specifically the modes of interaction between the two airfoils against different initial conditions which are validated by numerical calculations based on commercially available software. We then examine stability and transient dynamics by assuming small deflections and applying multiple-scale analysis to obtain a stability condition. The condition is attained via the compatibility equations of the orthogonal spatial modes of the first-order theory. We then examine stability and transient dynamics by assuming small deflections and applying multiple-scale analysis to obtain a stability condition. The condition is attained via the compatibility equations of the orthogonal spatial modes of the first-order theory.

3:39PM A09.00004 Deformations, forces and flow field around a compliant membrane disk. ASIMANSHU DAS, VARGHESE MATHAI, KENNETH BREUER, School of Engineering, Brown University — Highly compliant membranes exhibit large scale deformations and can alter the nature of the flow with which they interact. We focus on understanding the kinematics and dynamics of circular compliant membranes with varying shear modulus, G, placed head-on in a uniform flow. The experiments were carried out in a closed-loop low-speed wind tunnel with Reynolds number in the range of $10^4$ to $10^5$. We measure the average and fluctuating properties of the compliant structure, including its deformation and drag forces. The membrane deforms into parachute-like shapes depending on the value of a dimensionless number - the Aerelastic number, $Ae$ - which measures the relative importance of elastic and aerodynamic stresses. With decreasing $Ae$ (either higher speed, or a softer membrane), the membrane evolves from a flat circular disk-like shape to a nearly hemispherical shape. The drag coefficients vary from 1.1 to 1.4. We provide comparisons with the flow-induced forces on rigid shells of similar shape.

3:52PM A09.00005 Lift and Thrust Measurements on a Flapping Membrane Foil. GALI ALON TZEZANA, VARGHESE MATHAI, KENNETH BREUER, School of Engineering, Brown University — Flapping compliant membrane wings demonstrate increased lift and thrust when compared to rigid wings, particularly when flapping close to the natural frequency of the wing. However, if the wing is too compliant, the forces are decreased. Here, we performed experiments to measure the hydrodynamic forces acting on a heaving compliant membrane in a water flume facility, at a Reynolds number of 20,000-60,000. By varying the membrane’s elastic modulus, thickness and pre-stretch, we modify the natural frequency of the membrane. We observe linear and nonlinear behaviors of the forces and membrane deformations with respect to the Strouhal number and natural frequency. For cases with small deformations, we compare the experimental results with a linear, small amplitude potential flow based model. Finally, we discuss the flow structure and wake patterns obtained from Particle Image Velocimetry (2-D PIV) measurements, and their relation to propulsive performance.

4:05PM A09.00006 Large-amplitude membrane dynamics in inviscid flow. CHRISTIANA MAVROYIAKOMOU, SILAS ALBEN, University of Michigan — We study the dynamics of thin membranes—extensible sheets with negligible bending stiffness—and their behavior in an inviscid background flow. This is a benchmark fluid-structure interaction that has previously been studied mainly in the small-deflection limit, where the flat state may be unstable. Related work includes the shape-morphing of airfoils and bat wings. We study the initial instability and large-amplitude dynamics with respect to three key parameters: membrane mass density, stretching rigidity, and pretension. When both membrane ends are fixed, the membranes become unstable by a divergence instability and converge to steady deflected shapes. With the leading edge fixed and trailing edge free, divergence and/or flutter occurs, and a variety of periodic and aperiodic oscillations are found. With both edges free, the membrane may also translate transverse to the flow, with steady, periodic, or aperiodic trajectories.

4:18PM A09.00007 Efficiency Enhancements in Hydrokinetic Energy Harvesting Achieved Using a Compliant Membrane Hydrofoil. VARGHESE MATHAI, GALI ALON TZEZANA, KENNETH BREUER, School of Engineering, Brown University — Hydrokinetic energy harvesting using an oscillating hydrofoil has recently received increased attention as an alternative to conventional rotary turbines. One of the challenges in the development of commercially viable flapping foil technology is to attain cycle efficiencies comparable to those of rotary turbines. Here we experimentally study the energy harvesting performance of a compliant membrane hydrofoil undergoing heaving and pitching oscillations in a uniform flow. Membrane foils with different properties: elastic modulus, thickness and pre-stretch were fabricated and tested in a water flume facility. The Reynolds number based on the chord length and free stream velocity was $Re = 5 \times 10^4$, and the reduced frequency $f^* \in [0.1, 0.2]$. When compared to a rigid symmetric hydrofoil, the membrane foil is able to dynamically adapt its shape and camber during each oscillation cycle, yielding up to 50% higher lift forces and 30% improvement in cycle efficiency. The flow structure and wake patterns obtained from Particle Image Velocimetry (2-D PIV) measurements will also be discussed.

3:00PM A10.00001 On the Morison equation and heave plate hydrodynamics, CURTIS RUSCH, University of Washington, BENJAMIN MAURER, University of Washington Applied Physics Laboratory, BRIAN POLACYE, University of Washington — Ocean wave energy converters often use a submerged reaction body, such as a heave plate, to generate electricity from wave motion. Analysis of heave plate hydrodynamics typically utilizes the Morison equation to estimate the contributions of drag and inertia to hydrodynamic force, neglecting further components, such as the vortex force discussed extensively by Saripaya. We perform laboratory experiments to evaluate the representativeness of a Morison decomposition over a range of operational and survival states, representing Keulegan-Carpenter (KC) numbers of 0.5 to 4. Driving a hexagonal conic heave plate in regular sinusoidal motion with 17 combinations of period and amplitude, we measure force at the plate and visualize the surrounding flow. Using the Morison equation, we calculate both constant coefficients of drag and added mass and phase-dependent variable coefficients. We find that constant coefficients adequately describe hydrodynamic force at low KC number, but this accuracy decreases with increasing KC number. Variable coefficients accurately reconstruct hydrodynamic forces over the full range of KC numbers investigated. We discuss this discrepancy in the context of the vortex term using dye visualization, and discuss implications for wave energy converter design.

1NSF Graduate Research Fellowship Program and the Naval Facilities Engineering Command

3:13PM A10.00002 Vortex-Induced Vibration and Galloping of a Flexible Square Prism, RONALD COLMON, YAHYA MODARRES-SADEGHI, University of Massachusetts Amherst — We have studied flow-induced oscillations of a tension-dominated flexible beam with a square cross-section placed perpendicular to the incoming flow. The prism with an aspect ratio of 32 was fixed at its both ends and placed in the test-section of a recirculating water tunnel. The Reynolds number was varied from 400 to 2400. Tracker points were evenly spread along the length of the prism, on two perpendicular sides, in order to measure the prism’s displacements in the crossflow (CF) and inline (IL) directions. Displacements of these points were tracked using two synchronized high-speed cameras. It was found that at low reduced velocities the first and then the second structural modes were excited in the CF direction, together with the second and the fourth modes in the inline direction, resulting in vortex-induced vibration with “figure 8” trajectories. At higher reduced velocities, the amplitude of oscillations increased dramatically, and galloping-type oscillations were observed.

1Spaulding-Smith Diversity STEM Fellowship

3:26PM A10.00003 The formation process of leading and secondary vortices, DIEGO FRANCESCANGELI, KAREN MULLENERS, EPFL — Vortex formation is a limiting process. When a plate is accelerated from rest or fluid is impulsively ejected from a piston-cylinder apparatus, a primary or leading vortex grows in size and strength up to a limit when it pinches-off. Beyond this point, secondary vortices akin to a Kelvin-Helmholtz instability are generated. These secondary vortices are similar to each other but smaller in size and lower in strength than the leading vortex. The motivation to understanding the difference between the leading and secondary vortices, leads us to study the formation process of vortices around a moving rectangular plate in a quiescent fluid. Eulerian and Lagrangian methods are used to track vortices and determine their circulation, vorticity distribution, and size from experimental velocity field data. The experimental data is further compared with different theoretical vortex models to elucidate the differences between the formation process of the leading and the secondary vortices.

3:39PM A10.00004 Dynamics and flow structures in the vortex-induced vibration of a curved flexible cylinder, BANAFSHEH SEYED-AGHAZADEH, Darmouth Campus, University of Massachusetts, BRIDGET BENNER, XHINO GJOKOLLARI, YAHYA MODARRES-SADEGHI, University of Massachusetts, Amherst — Vortex-induced vibration of a curved flexible circular cylinder placed in the test section of a re-circulating water tunnel and fixed at both ends was studied, experimentally. Both the concave and the convex orientations (with respect to the oncoming flow direction) were considered. The cylinder was tension-dominated by its own weight with an aspect ratio of 86 and a low-mass ratio of 3.7. High-speed imaging technique was employed to record the oscillations of the cylinder in the crossflow direction for a reduced velocity range of $Re = 370-2400$. Mono- and multi-frequency responses as well as transition from low mode numbers to high mode numbers are observed. Regardless of the type of curvature, both odd and even mode shapes are excited in the crossflow directions. However, the response of the system, in terms of the excited modes, amplitudes and frequencies of oscillations, is observed to be sensitive to the direction of curvature (concave vs. convex), in particular at higher reduced velocities where mode transition happens. Hydrogen bubble image velocimetry flow visualization was conducted at multiple points along the length of the curved cylinder. Intermittency in the vortex shedding patterns in the wake of the cylinder and alternating wake along the cylinder are observed. The observed altering wake corresponds to the multi-modal excitation and dominant mode transition along the length of the cylinder.

3:52PM A10.00005 Decay of vortex rings in spheroidal confined domains, MILAD SAMAEED, ARVIND SANTHANAKRISHNAN, Oklahoma State University — Recent studies studied the decay of vortex rings in radially confined domains; however, the vortex ring decay process in spheroidal confinement (axial and longitudinal confinement) remains unclear. This type of confinement is observed in the vortex rings formed during filling of the human cardiac left ventricle. We hypothesized that the rate of circulation decay increases in more axially confined domains. A piston-cylinder setup was used to generate vortex rings for this study. 2D time-resolved PIV was used to quantify the flow fields within three different aspect ratios of spheroidal silicone models (0.8, 1, and 1.25) under different filling duration, Reynolds number, and deceleration time. The formation number and peak circulation remained unaffected regardless of model shape. However, for the cases with the same filling duration, the vortex ring pinched-off earlier by shortening the acceleration time. We observed a higher rate of decay for the model with a lower aspect ratio (more axially confined).

3:00PM A11.00001 Direct Calculation of Eddy Viscosity of Turbulent Channel Flow

supported by Boeing.

3:13PM A11.00002 A minimal quasilinear approximation of turbulent channel flow

YOUNG-YUN HWANG, Department of Aeronautics, Imperial College London, BRUNO ECKHARDT, Fachbereich Physik, Philips-Universität Marburg — Townsend’s model of attached eddies for boundary layers is analysed within a quasi-linear approximation. The velocity field is decomposed into a mean profile and fluctuations. While the mean is obtained from the nonlinear equations, the fluctuations are modelled by replacing the nonlinear self-interaction terms with an eddy-viscosity-based turbulent diffusion and a stochastic forcing. The colour and amplitude of the stochastic forcing are then determined self-consistently by solving an optimisation problem which minimises the difference between the actual Reynolds shear stresses and the model. When applied to turbulent channel flow in a range of friction Reynolds number from $Re_f = 500$ to $Re_f = 20000$, the resulting turbulence intensity profile and energy spectra exhibit exactly the same qualitative behaviour as DNS data throughout the entire wall-normal location, thereby reproducing the early theoretical predictions of Townsend and Perry within a controlled approximation to the Navier-Stokes equation.

3:26PM A11.00003 Minimal-span direct simulation of transient, accelerating channel flows and application with wall riblets.

SAURABH PARGAL, Student, JUNLIN YUAN, Assistant professor, GILES BRETON, Professor — Minimal-span simulation of wall turbulence is an attractive approach for reducing simulation cost when focusing on near-wall phenomena associated with frictional drag modification due to surface riblets or roughness. We evaluate the capability of such simulations for a periodic smooth-wall channel flow subjected to rapid acceleration from a friction Reynolds number of 180 to one of 420. Compared to a full-span simulation, the single-point statistics, two-point correlations and spectral analyses indicate that the minimal span is sufficient to capture the pseudo-laminarization phenomenon, since the stabilization effect of the increased ensemble-averaged shear is confined to the near-wall region. As the increased shear is relaxed, the retransition to a new equilibrium state, though starting from the wall, is slightly delayed compared to that in a full channel. The wall is then covered with saw-tooth riblets of a uniform height, which is 7.5 wall units at the start of, and 17.5 at the end of acceleration. Lower Reynolds stresses (in wall units) and a slower retransition are observed in the riblet flow, compared to a smooth-wall channel flow. The results demonstrate both advantages and limitations of minimal-span simulations of non-equilibrium wall turbulence.

3:39PM A11.00004 Orr-Sommerfeld and Squire modes in fully-turbulent channel flow

RYAN MCMULLEN, KEVIN ROSENBERG, BEVERLEY MCKEON, Caltech — The Orr-Sommerfeld (OS) and Squire (SQ) operators from classical stability literature have gained renewed interest in the context of linear analyses of turbulent shear flows. We demonstrate that the recently-proposed decomposition of the resolvent operator into two distinct families related to the OS and SQ operators (Rosenberg & McKeon, 2019) results in accurate low-order representations of the second-order statistics in turbulent channel flow. It is shown that the ability to match all components well is due to the isolation of the v response in the OS modes. This enables competition between the OS and SQ vorticity, which is interpreted as a phase difference between the two sets of modes. Additionally, the relative Reynolds number scalings for the two families of resolvent weights are derived for the universal classes of resolvent modes presented by Moarref et al. (2013). Implications for modeling nonlinear interactions in wall-bounded turbulence are discussed.

3:52PM A11.00005 Direct Numerical Simulations of transverse acoustic forcing in fully developed channel flow turbulence

ANDREA GRUBER, SINTEF, MELISSA KOZUL, JAMES R. DAWSON, NTNU — Hydrogen-firing of gas turbines is a promising direction for clean and efficient carbon-free power generation. However, premixed combustion of undiluted hydrogen in low-emission combustion systems can result in unstable operating modes for gas turbines and their development must solve issues posed by flame flashback (off-design upstream propagation), and flame combustion dynamics (coupling of longitudinal or transversal acoustic waves with fluctuating heat release). The causal relationship between longitudinal acoustically-induced bulk flow fluctuations (due to combustion dynamics) and the occurrence flashback in gas turbine burners has been established for some time (Fritz et al., J Eng Gas Turbines Power 2004) while the key role of the near-wall ‘streaks’ of the turbulent boundary layer in controlling the flashback propagation was only explained more recently (Gruber et al., J Fluid Mech 2012). In this context, it is important to examine the effect of transversal acoustic waves, resulting from azimuthal modes resonating in annular combustors, on the characteristic streaky structure of near-wall turbulence. We present DNS results from an idealized channel flow configuration that employs periodic boundary conditions in the streamwise and spanwise directions, where sinusoidal pseudo-acoustic waves are imposed transversally to the bulk flow, mimicking a limit cycle. We report the response of the near-wall streaks of the velocity field to the frequency and amplitude of the imposed acoustic waves.

4:05PM A11.00006 Lifetimes of the large-scale motions in channels up to $Re_f \approx 5000$

MIGUEL ENCINAR, ALBERTO VELA-MARTIN, JAVIER JIMENEZ, Universidad Politecnica de Madrid — The energy spectra of (wall-bounded) turbulent flows is unmistakeably one of the most important tools in turbulent research. Due to past limitations of computational resources, direct numerical simulations have traditionally focused on the computation of the spatial spectra, neglecting its temporal counterpart. We compute the spatio-temporal spectra of the large scales (larger than one fifth of the channel half-height) of channels up to $Re_f \approx 5000$. Using the spectra, it is possible to extend the definition of ‘correlation time’ to provide a meaningful estimation of the lifetime for every spatial wavelength, and at every height. We find the lifetimes to increase with the distance to the wall and with the stream and spanwise wavelengths. There is almost no difference between in the lifetime of a given wavelength between velocity components. Nevertheless, the expected lifetime of each component is different due to the difference in their energy spectra, i.e. the streamwise component lives longer because has more energy in long wavelengths. We also found that the lifetimes scale across Reynolds numbers with the channel half-height and the bulk velocity, instead of the friction velocity.

4:18PM A11.00007 Turbulent mean flow profile in 2D channel flow. VILDA MARKEVICIUTE, RICH KERSWELL, University of Cambridge — Two-dimensional channel flow is well known to exhibit chaotic behaviour in which structures common to turbulent flows such as vorticity sweeps, large-scale intermittency, and quasi-periodic bursting are observed (Jimenez 1990). Recently, Falkovich and Vladimirova (2018) have found that the time-averaged turbulent mean flow at constant pressure gradient exhibits a remarkably simple wave-like structure which is known to exist for low Reynolds numbers (Re), including below the linear instability threshold (Re=5772). Trying to confirm this finding, here we revisit this flow imposing constant mass flux driving instead. At least in short channels, we find unexpectedly long-lived asymmetric states beyond a critical Reynolds number where the turbulence is confined to one of the channel walls. This poses an interesting question of how long one needs to wait to recover the expected symmetric mean flow or whether there really is bistability of turbulent states centred on one or other of the walls.

Saturday, November 23, 2019 3:00PM - 4:31PM — Session A12 Separated Flows: General 303 - Xiaofeng Liu, San Diego State University

3:00PM A12.00001 Bursting of Laminar Separation Bubbles, O. N. RAMESH, ABHIJIT MITRA, Indian Institute of Science, Bangalore — The transition of a small laminar separation bubble (LSB) to a long LSB is called bursting, and this might be abrupt in some airfoils. Bursting is manifested as a significant departure of the surface pressure distribution from its inviscid flow distribution, with a considerable drop in the peak suction pressure. In our present study of flow over Eppler367 at an angle of attack of 8 degrees, we have chosen three representative LSBs: long, transitional and short bubbles. Bursting has been often linked to the onset of absolute instability of the separated shear layer. On impulsively forcing these three bubbles, it is found that all the bubbles are convectively unstable in the high-frequency range. However, all of them, though an order of magnitude lesser in short bubbles, show tendencies of absolute instability in the low-frequency range. A self-limiting behavior for the unforced transitional and long LSBs is evident. An explosive growth of high-frequency activity is found to be strongly correlated to the low-frequency flapping motion of the longer bubbles. Negative production of turbulent kinetic energy is responsible for the runaway effect observed during bursting.

3:13PM A12.00002 Sudden kinks in proper orthogonal decomposition modes of vorticity field for a turbulent flow past a ship topside subject to oscillatory motion. XIAOFENG LIU, San Diego State University, ANISH SYNDAY, NAPEI BI, Naval Surface Warfare Center Carderock Division, SAN DIEGO STATE UNIVERSITY COLLABORATION, NAVAL SURFACE WARFARE CENTER CARDEROCK DIVISION COLLABORATION — Complex flow fields above and around ship deck often exhibit a wide range of temporal and spatial features in fluid motion, which affects not only the ship performance, but also Launch and Recovery (L&R) of air vehicles. To characterize the complex turbulent flow over a ship topside, Time-Resolved Particle Image Velocimetry (TR-PIV) is used in a subsonic wind tunnel test with both stationary and oscillatory modes of the ship model. The tests are conducted at a wind speed of 10.3 m/s and ship oscillations at a frequency of 2.0 Hz with an amplitude of 2.5 degrees. Proper Orthogonal Decomposition (POD) analysis, capable of extracting energetically and dynamically significant features of complex fluid flows, is applied to the time series of the planar velocity and vorticity distributions obtained by the PIV measurements. The POD analyses show that a novel phenomenon featuring significant sudden discontinuities in the vorticity POD mode pattern distributions dubbed as “kinks” is observed for the test model subject to oscillatory motion. In contrast, such kinks are not found in the vorticity POD modes for the test case without the model oscillatory motion, nor the velocity POD modes for both the stationary and the oscillatory tests.

3:26PM A12.00003 Dynamics of the shear layers detaching from the upstream corners of an elongated rectangular cylinder, MARIA VITTORIA SALVETTI, ALESSANDRO MARIOTTI, ELENA PASQUALETTO, BENEDETTO ROCCHIO, DICI, University of Pisa — The behavior and the dynamics of the shear layers detaching from a rectangular cylinder, having chord-to-depth ratio equal to 5, are investigated through highly-resolved large-eddy simulations and experimental velocity and pressure measurements. The considered configuration, which is the object of the benchmark BARC, is characterized by flow reattachment on the cylinder sides in the rear part of the body. It is shown that the mean length of the separated region, and hence the velocity and pressure measurements. The considered configuration, which is the object of the benchmark BARC, is characterized by flow reattachment on the cylinder sides in the rear part of the body. It is shown that the mean length of the separated region, and hence the shear-layer transition length. The characteristic frequencies of the shear-layer dynamics are also investigated and compared with those characterizing the vortex shedding in the wake and the unsteady aerodynamics loads. Finally, the effects of small rounding of the upstream corners on the previously mentioned quantities and phenomena are briefly analyzed.

3:39PM A12.00004 How dynamic is static stall? Julien DEPARDAY, KAREN MULLENNERS, UNFoLD, Institute of Mechanical Engineering, Ecole Polytechnique Federale de Lausanne, CH-1015 Lausanne, Switzerland — The static stall angle is the critical angle of attack above which the flow detaches from the airfoil’s surface. When the static stall angle is exceeded, the transition from attached to separated flow is not instantaneous. The transient development is characterized by different stages and time-scales similar to the dynamic stall flow development stages and stall delays. Static stall can be seen as an extreme case of dynamic stall where there is no motion during the stall development. On a NACA0018 profile, we initiated static stall by an increase in the angle of attack from 0.3° to 0.3° above the static stall angle in 10% of a convective time unit. We measured the time-resolved flow field and aerodynamic forces and analysed their temporal evolution. The transition time from attached to separated flow is longer in the static stall case than in the dynamic stall cases even though the topological flow development is comparable. Special emphasis is directed towards linking the inception of stall to the motion of the leading edge stagnation point. These results will serve as a basis to improve low-order models based on indicial response.

3:52PM A12.00005 Role of an active trailing-edge flap of a pitching airfoil undergoing dynamic stall1, GUOSHENG HE, EPFL, LARS SIEGEL, ARNE HENNING, DLR, KAREN MULLENNER, EPFL — The flow around a pitching NACA0015 airfoil with an active trailing-edge flap is investigated using two-dimensional time-resolved particle image velocimetry and surface pressure measurements. The Reynolds number based on the chord length is about $5.5 \times 10^5$. The airfoil is pitching around the static stall angle of attack of $20^\circ$ and the flap is either oscillating around the symmetrical plane at $\beta = 0^\circ$ or fixed at a constant deflection angle. The pitching of the airfoil and the deflection of the flap can be individually controlled in terms of mean angle, oscillating amplitude, frequency and initial phase angle. Below the stall angle, the lift of the static airfoil increases proportionally with the increase of flap deflection angle in the investigated range of $-20^\circ \leq \beta < 20^\circ$. Variations of the phase delay between the oscillations of the main airfoil and the flap lead to a rotation, expansion, or contraction of the dynamic stall lift curves. Higher-order harmonic flap oscillations for the pitching airfoil result in bending or twisting of the lift curves. Quantitative evidence has been extracted from the PIV data to help elucidate the modified aerodynamic characteristics of the pitching airfoil manipulated by the active flap.

4:05PM A12.00006 Enhancement of Slat Airfoil Configuration using Invasive Weed Optimization Framework coupled with Artificial Neural Networks,1, SUSHRUT KUMAR, PRIYAM GUPTA, RAJ KUMAR SINGH, Delhi Technological University — This research attempts to develop an optimization scheme by integrating Genetic Algorithm and Artificial Neural Network (ANN) - surrogate model which was successfully implemented to optimize Leading Edge Slat shape and configuration. The optimization model used Invasive Weed Optimization. Bezier curves were used as an aerodynamic shape parameterization method to ensure the generation of smooth-contoured slat profiles. Geometry, Overhang, Depth and Deflection were taken as the defining parameters for each individual. These parameters were varied within a range which is 3.4% to 15% of slat chord for Overhang, -5% to 4% of slat chord for Depth, -5% to 5% of initial deflection for Deflection and the ordinate of shape control points had a variation of $\gamma$ to $\gamma$3. The standard deviation decreases non linearly from 6 to 0.005 with a modulation index of 3. Multiple Computational Fluid Dynamics simulations were run for each individual under various operating conditions to evaluate their fitness (lift to drag ratio). The data generated from this process was used as training and test sets for the ANN. Shape control points, angle of attack, Reynolds number and operating conditions were taken as input parameters for the neural network to predict lift to drag ratio. The developed technique showed approximately 85% improvement in the time taken and allowed algorithm to better explore design space.

1We acknowledge Fluid Systems Lab, Delhi Technological University for providing access to the computing facility for performing the simulations.

4:18PM A12.00007 Resolvent analysis of laminar separation bubble over an airfoil at high Reynolds number using discounting and randomized linear algebra1, CHI-AN YEH, University of California, Los Angeles, STUART BENTON, Air Force Research Laboratory, Wright-Patterson Air Force Base, KUNIHIKO TAIRA, University of California, Los Angeles, DANIEL GARMANN, Air Force Research Laboratory, Wright-Patterson Air Force Base — We perform resolvent analysis to examine the perturbation dynamics over the laminar separation bubble (LSB) that forms near the leading edge of an airfoil at Re=5E5. While we focus on the LSB residing over 65% of the chord, the resolvent operator is constructed about the global mean flow over the airfoil, avoiding issues due to domain truncation. Moreover, randomized SVD is adopted in the analysis to relieve the computational cost for the high-Re global baseflow. To examine the local physics over the LSB, we consider the use of exponential discounting to limit the time horizon that allows for the instability to advect along the baseflow. In addition to discounting, we also examine the use of a spatial mask that highlights the LSB in the analysis. We find that discounting is required to reveal the stability characteristics of the LSB due to the unstable baseflow, regardless of the use of the mask. With discounting, the gain distribution over frequency accurately captures the spectral content over the LSB obtained from LES. The peak frequency also agrees with previous flow control results on suppressing dynamic stall. We show that discounted analysis is the appropriate approach for unstable baseflow and that randomized approach can expand global resolvent analysis to high-Re flows.

Saturday, November 23, 2019 3:00PM - 4:05PM – Session A13 Magnetohydrodynamics

3:00PM A13.00001 Inclined turbulent thermal convection in liquid sodium1, LUKAS ZWIRNER, Max Planck Institute for Dynamics and Self-Organization, RUSLAN KHALILOV, ILYA KOLESNICHENKO, ANDREY MAMYKIN, SERGEY MANDRYKIN, ALEXANDER PAVLINOV, ALEXANDER SHESTAKOV, ANDREY TEIMURAZOV, PETER FRICK, Institute of Continuous Media Mechanics, OLGA SHISHKINA, Max Planck Institute for Dynamics and Self-Organization — Inclined turbulent thermal convection at large Rayleigh numbers (Ra) in extremely small Prandtl-number (Pr) fluids is studied by measurements and high-resolution numerical simulations. The working fluid is liquid sodium (Pr about 0.0094) and the considered Ra is around $1.5 \times 10^7$. The convection cell is a cylinder with equal height and diameter, where one circular surface is heated and another one cooled. For the limiting inclination angle $\beta$, which correspond to Rayleigh-Benard convection ($\beta = 0$) and vertical convection ($\beta = \pi/2$), the scaling relations of the mean heat flux (Nusselt number Nu) with Ra are studied. Any inclination of the RBC cell leads to an increase of Nu; the maximal Nu is obtained, however, for a certain intermediate value of $\beta$. For small $\beta$, the large-scale circulation (LSC) exhibits a complex dynamics, with torsion and sloshing modes, which are suppressed for large $\beta$. When the LSC is twisted, the volume-average vertical heat flux is minimal, and it is maximal, when the LSC sloshing brings together the hot and cold streams of the LSC.

1The work is supported by the Deutsche Forschungsgemeinschaft (DFG), grants Sh405/7 (SPP 1881 Turbulent Superstructures) and Sh405/4 (Heisenberg fellowship) and the Leibniz Supercomputing Centre.
3:13PM A13.00002 Redescribing of Busse balloon on Rayleigh-Bénard convection imposed by horizontal magnetic field  
YUJI TASAKA, Hokkaido University, TAKATOSHI YANAGISAWA, JAMSTEC, TOBIAS VOGT, SVEN ECKERT, HZDR — Laboratory experiment of RBC was performed using GaInSn eutectic as a typical low Pr fluid with quasi-uniform horizontal magnetic field to elucidate how the Busse balloon describing stability of 2D rolls is modified by Lorenz force effect. Development of the flow from steady rolls to unsteady state were investigated with decreasing Chandrasekhar number $Q$ in a range, $2.5 \times 10^{-8} \leq Q \leq 1.9 \times 10^{-7}$ at fixed $Ra$ numbers, $7.9 \times 10^4 \leq Ra \leq 1.8 \times 10^5$, by ultrasonic velocity profiling. The velocity profile measurements showed the dynamic morphology of the oscillatory convection, 2D oscillation observed at the onset of oscillations, oscillations of recirculation vortex pairs between the main rolls, and synchronous motion of the main rolls. The measurements also suggested that the oscillation occurs at similar Reynolds numbers $Re \approx 900$ and may be caused by instabilities on the recirculation vortex pair. This finding suggests that the oscillations are essentially different from generally observed traveling waves described as the oscillatory instability considered in the Busse balloon. Power law found on the variation of $Re$ with $Q$ suggested the 2D oscillation is dominated by ratio between side wall Hartmann braking and buoyancy.

3:26PM A13.00003 Heat transfer and flow regimes in quasi-static magnetoconvection with a vertical magnetic field  
MING YAN, MICHAEL CALKINS, STEFANO MAFFEI, KEITH JULIEN, University of Colorado, Boulder , STEVEN TOBIAS, University of Leeds , PHILIPPE MARTI, ETH Zurich — Numerical simulations of Rayleigh-Bénard convection with an imposed vertical magnetic field are carried out over a broad range of Rayleigh numbers and magnetic field strengths. Three magnetoconvection regimes are identified: two of the regimes are magnetically-constrained in the sense that a leading-order balance exists between the Lorentz and buoyancy forces, whereas the third regime is characterized by unbalanced dynamics that is similar to non-magnetic convection. Each regime is distinguished by flow morphology, momentum and heat equation balances, and heat transport behavior. One of the magnetically-constrained regimes appears to represent an ‘ultimate’ magnetoconvection regime in the dual limit of asymptotically-large buoyancy forcing and magnetic field strength; this regime is characterized by an interconnected network of anisotropic, spatially-localized fluid columns aligned with the direction of the imposed magnetic field that remain quasi-laminar despite having large flow speeds. Heat transport is controlled primarily by the thermal boundary layer. Empirically, the scaling of the heat transport and flow speeds appear to be independent of the thermal Prandtl number within the magnetically-constrained regimes.

3:39PM A13.00004 Response of the Free Surface of an Electrically Conducting Liquid to a Magnetic Field  
SURESH MURUGAIYAN, COLIN ADAMS, BHUVANA SRINIVASAN, STEFANO BRIZZOLARA, Kevin T. Crofton Department of Aerospace and Ocean Engineering, Virginia Polytechnic Institute and State University — Response of the free surface of an electrically conducting liquid to a magnetic field that varies in space and time, is studied using numerical simulations. A fully implicit finite volume solver is used to solve magnetohydrodynamic equations. The equations are solved using a segregated approach on a collocated grid arrangement where all the variables are stored at the cell centers. The PISO (Pressure-Implicit with Splitting of Operators) algorithm is used to solve the equation of fluid momentum with the Rhie and Chow momentum interpolation technique to overcome oscillations in pressure. The equation of magnetic field evolution is solved in the same manner as the equation of fluid momentum by introducing an artificial pressure term. The method of Volume Of Fluid (VOF) is used to track the interface between the two immiscible fluids. Numerical experiments concerning the effect of high density ratio on a two-fluid magnetohydrodynamic system shall be carried out.

3:52PM A13.00005 Instability in Electromagnetically Driven Flow between Concentric Spheres1  
SAUL PIEDRA, CONACYT-CIDESI Centro Nacional de Tecnologías Aeronáuticas, ALDO FIGUEROA, IVAN RIVERA, CONACYT-Centro de Investigacion en Ciencias, Universidad Autonoma de Estado de Morelos, PHYSICS OF CONTINUOUS MEDIA LABORATORY TEAM — The rotational flow continuously driven by electromagnetic forcing of an electrolytic fluid in the gap of concentric spheres set-up is studied experimentally and theoretically. The driving Lorentz force is generated by the interaction of a DC electric current radially injected and the dipolar magnetic field produced by a permanent magnet. Velocity profiles in the equatorial plane were obtained using Particle Image Velocimetry (PIV), whereas the radial velocity component of the flow was recorded with Ultrasonic Doppler Velocimetry (UDV). A fully three-dimensional numerical model that takes into account the dipolar magnetic field and the radial dependency of the applied current was developed. The model reproduces the main features of the electromagnetically forced flow. For small injected currents, a quite axisymmetric equatorial recirculation formed mainly by diffusive momentum transport was found. For currents above 200 mA, which corresponds to a Re > 1340, instabilities of the inner boundary layer are observed and the flow becomes three-dimensional and time dependent.

Session A14 Convection and Buoyancy-driven Flows: Multiphase 307/308 - Raymond Shaw, Michigan Technological University

3:00PM A14.00001 Heat flux in moist and cloudy Rayleigh-Bénard convection1  
RAYMOND SHAW, SUBIN THOMAS, PRASANTH PRABHAKARAN, WILL CANTRELL, Michigan Technological University — Heat flux in moist and cloudy Rayleigh-Bénard convection consists of both sensible heat flux (temperature flux) and latent heat flux (water vapor flux and condensation/evaporation growth of cloud droplets). Under cloudy conditions, condensation of water vapor away from the boundaries is a source term for temperature and a sink term for water vapor. Thus, the condensation of water vapor reduces the mean water vapor concentration in the bulk and increases the mean bulk temperature. This in turn enhances the latent heat flux and lowers the sensible heat flux passing through the system. We investigate the effect of condensation rates in a cloudy Rayleigh-Bénard convection system, using an experimentally validated LES model. We propose a modified heat flux that remains conserved under these conditions, and we explore the influence of varying cloud properties such as cloud droplet concentration (modulated via the aerosol properties) and liquid water mixing ratio.

1This work is supported by NSF grant AGS-1754244.
3:13PM A14.00002 Effects of the Large-Scale Circulation on Temperature and Water Vapor Distributions in the Michigan Tech II-Chamber

JESSE ANDERSON, GREGORY KINNEY, PRASANTH PRABHAKARAN, SUBIN THOMAS, RAYMOND SHAW, WILL CANTRELL, Michigan Technological University — In Rayleigh-Bénard convection, it is well known that within the turbulent motion a mean flow forms, commonly referred to as the large-scale circulation. We report experimental results on the nature of this circulation and its impact on the temperature and water vapor fields in Michigan Tech’s II-chamber (Aspect ratio=2 and Pr = 0.7) under dry, moist (no injection of aerosols) and cloudy conditions. The II-chamber is designed to study aerosol-cloud interactions in a turbulent environment. These interactions are strongly influenced by the temperature and water vapor fields because they control the growth rates of each cloud droplet. The differential growth rates between droplets could result in a broadening of the cloud droplet distribution which is important for the onset of precipitation in clouds. We report various features of the circulation - an azimuthal oscillation, a sloshing mode, and a possible compression along the axis of the main roll. In addition, the temperature and water vapor concentration were measured and analyzed with respect to the orientation to the large-scale circulation. The distributions were found to be positively skewed along the updraft and negatively skewed along the downdraft.

3:26PM A14.00003 A Lagrangian network-based analysis of evaporative droplets in Rayleigh-Bénard convection

THEO MACMILLAN, DAVID RICHTER, University of Notre Dame — Rayleigh-Bénard convection is characterized by different scales of coherent motion, from a large-scale circulation (LSC) to transient thermal plumes. To better understand the mixing behavior of evaporative droplets in such a system, we assemble a time-evolving weighted network from the droplets’ individual trajectories using direct numerical simulation (DNS) with Lagrangian droplet tracking. By varying the time over which the network is assembled, we detect both the LSC and transient thermal plumes in the spectral gap of the network’s Laplacian while accurately determining their respective time scales. Using tools developed for the analysis of complex graphs, we are able to objectively characterize the limiting cases (i.e., fast microphysics dominated and slow microphysics dominated mixing) and the interplay between short time-scale coherent structures and the LSC in the dynamics of the droplet ensemble. This has implications for understanding, for example, essential mechanisms of the formation of rain, including cloud entrainment and droplet spectra broadening processes such as stochastic condensation.

3:39PM A14.00004 Dynamics of air bubbles in Rayleigh-Bénard Convection: pair dispersion and effect of initial separation

LEONARDO P CHAMORRO, JIN-TAE KIM, University of Illinois at Urbana-Champaign, JAEWOOK NAM, Yonsei University, SHIKUN SHEN, University of Illinois at Urbana-Champaign, CHANGHOON LEE, Yonsei University — Laboratory experiments were performed to uncover the dynamics of bubbles in Rayleigh-Bénard (RB) convection at Ra=1.1x10^10, where streams of 1-mm bubbles were released at various locations from the bottom of the RB tank along the path of the roll structure. 3D particle tracking velocimetry was used to track simultaneously a relatively large number of bubbles, and to quantify the pair dispersion for various initial separations in the range of 25 ≤ η ≤ 225, where η is the local Kolmogorov length scale. Numerical simulation was carried out to further study the role of the bubble’s path instability. Results show that the pair dispersion underwent a transition phase similar to the ballistic-to-diffusive (t^2-to-t) regime in the vicinity of the cell center; however, it approached to a bulk behavior t^1.5 in the diffusive regime as the distance away from the cell center increased. At small initial separation, the pair dispersion exhibited t^1 in the diffusive regime, indicating that the convective turbulence reduced the amplitude of the bubble’s path instability. At large initial separations, the pair dispersion exhibited t^2, showing the effect of the roll structure.

3:52PM A14.00005 Formation of vortex rings and drops at particle-laden fronts in thermally stratified environments

CHEN-YEN HUNG, YI-JU CHOU, National Taiwan University — We conduct numerical simulations to investigate the formation of drops and vortex rings at particle-laden fronts descending in density stratified environments. We show that the temporal evolution can be divided into double diffusion, acceleration, and deceleration phases. The acceleration phase is a result of the vanishing temperature perturbation in the drop during the descent in the layer of uniform temperature. The drop decelerates because it transforms into a vortex ring, whose motion follows the similarity assumption. A theoretical drag model is presented to predict the spherical drop speed with the low drop Reynolds number. In conjunction with the similarity argument for the motion of the vortex ring, our drag model shows good agreement in predicting the drag coefficient for the drop after the drop becomes spherical. Comparison of our drag model with simulations under various bulk conditions and previous experimental results shows good model predictability for the descending speed of drops.

4:05PM A14.00006 ABSTRACT WITHDRAWN

4:18PM A14.00007 Self-sustained biphasic catalytic particle turbulence

ZIQI WANG, Tsinghua University, VARGHESE MATHAI, Brown University, CHAO SUN, Tsinghua University — Turbulence is known for its ability to vigorously mix fluid and transport heat. While over a century of research for enhancing heat transport, few have exceeded the inherent limits posed by turbulent-mixing. Here we have conceptualized a kind of “active particle” turbulence machine: we find that by adding a minute payload of heavy liquid (1% hydrofluoroether) to a water-based turbulent convection system, remarkably, high efficient biphasic dynamics is born, which supersedes turbulent heat transport by up to 500%. The system is unique in that it operates on a self-sustained regime as the distance away from the cell center increased. This work was supported by Natural Science Foundation of China under grant nos. 91852202, 11861131005, 11672156.: 1Department of Energy and Power Engineering, Tsinghua University 2School of Engineering, Brown University 3Department of Energy and Power Engineering, Tsinghua University
In the near field has a suppressive effect on shear layer growth as well as the development of the counter-rotating vortex pair (CVP) and this behavior of Reacting Jet in Crossflow systems can be studied by considering the behavior of coherent structures and their formation and growth.

These experimentally determined coefficients can be used to refine Reynolds-Stress models of atmospheric flows in the presence of a volcanic plume. Currently with Exponent

GREG SAKRADSE, GREGORY SAKRADSE, Portland State University, STEPHEN SOLOVITZ, Washington State University Vancouver, RAUL BAYOAN CAL, Portland State University — Prediction of the development of jets in cross-flow has many useful applications in various fields such as chemical mixing and volcanic plume models. Most models used to predict the growth assume irrotational flow when both atmospheric and high Reynolds number flows are not. Simple laboratory experiments of air jets in crossflow downstream of an active grid system are used to simulate uniform turbulent inflows. A jet of air is injected orthogonally into a closed-loop wind tunnel with several cross-flow velocities and high Reynolds number. Results show that the jet has multiple pathways to instability; non-modal interactions are examined on their multiple time-scales. Helical actuations of the transverse modes, as well as axisymmetric and non-axisymmetric modes is studied. Adjoint modes show that the upstream shear-layer is most sensitive along the upstream side of the jet. High sensitivity downstream modes are sensitive in the cross-flow boundary layer. The transverse jet has multiple pathways to instability; non-modal interactions are examined on their multiple time-scales. Helical actuations of the transverse jet is being studied; these results will be discussed.

Supported by AFOSR.

DNS, stability and sensitivity of the low-speed transverse jet, SAMANTHA HAREL, KRISHNAN MAHESH, University of Minnesota — DNS, tri-global stability and adjoint analysis are performed for a jet in cross-flow (JICF) using a novel capability developed on unstructured grids and parallel platforms. Linear stability analysis reveals that upstream shear-layer modes have frequencies that match simulation and experiment. The relative importance of upstream and downstream shear layer modes, as well as axisymmetric and non-axisymmetric modes is studied. Snapshots are used to visualize the jetties of the jet and describe the trajectory and shear layer expansion are quantified and compared. Analysis is then focused on the evaluation of the dissipation and eddy viscosity for the purpose of refining $k-\epsilon$ modeling parameters. Identifying the differences turbulent cross-flow has on development of the jet and lee-side wake region provides more details on the important features necessary for accurate prediction of the spread and entrainment.

3:26PM A15.0003 The role of turbulent inflow on the development of a jet in cross-flow

GRAHAM FREEDLAND, GREG SAKRADSE, Portland State University, STEPHEN SOLOVITZ, Washington State University, RAUL BAYOAN CAL, Portland State University — Prediction of the development of jets in cross-flow has many useful applications in various fields such as chemical mixing and volcanic plume models. Most models used to predict the growth assume irrotational flow when both atmospheric and high Reynolds number flows are not. Simple laboratory experiments of air jets in crossflow downstream of an active grid system are used to simulate uniform turbulent inflows. A jet of air is injected orthogonally into a closed-loop wind tunnel with several cross-flow velocities and three active grid settings to simulate a range of turbulent conditions. Mean flow statistics and Reynolds stresses are computed using PIV data to identify key regions of interaction. The flow-fields are reoriented to provide components normal and tangent to the centerline of the jet and descriptions of the trajectory and shear layer expansion are quantified and compared. Analysis is then focused on the evaluation of the dissipation and eddy viscosity for the purpose of refining $k-\epsilon$ modeling parameters. Identifying the differences turbulent cross-flow has on development of the jet and lee-side wake region provides more details on the important features necessary for accurate prediction of the spread and entrainment.

3:39PM A15.00004 The spatial evolution of anisotropy along a jet in cross-flow

GREGORY SAKRADSE, GRAHAM FREEDLAND, RAUL BAYOAN CAL, Portland State University, STEPHEN SOLOVITZ, Washington State University Vancouver, Volcanic plumes present a unique challenge in the realm of atmospheric flow modelling, and many current models rely on general parameters applied to a wide range of flows. Improvements in modelling can be made by tuning model parameters to specific flows with experimental data. In laboratory conditions a volcanic plume can be approximated as a buoyant jet interacting with a cross-flow. The present work examines a round jet emitted into a cross-flow. Stereo PIV is used to directly measure three components of velocity in the near to medium field of the jet on a plane parallel to the cross-flow and on the central axis of the jet. Buoyant, neutrally buoyant and negatively buoyant cases are considered. The state of anisotropy is determined along lines parallel to the outer edges of the jet shear layers, and the progression of of the state of anisotropy is examined on an Anisotropy Invariant Map (AIM). The development in space of the state of anisotropy is used to refine coefficients in both linear and non-linear return to anisotropy models for the transport of the anisotropy tensor. These experimentally determined coefficients can be used to refine Reynolds-Stress models of atmospheric flows in the presence of a volcanic plume.

3:52PM A15.00005 Flame Position-Shear Layer Offset Effects on Jet in Crossflow Dynamics

VEDANTH NAIR, VISHAL ACHARYA, TIM LIEUWEN, Georgia Institute of Technology — The dynamics and mixing behavior of Reacting Jet in Crossflow systems can be studied by considering the behavior of coherent structures and their formation and growth. This study aims to understand the influence of heat-release on the growth of shear layer vortices (SLV) for a non-premixed, reacting jet in crossflow (RJICF) configuration. Two reacting cases are considered: pure methane jet into a crossflow of air (flame lies outside the jet shear layer) and a diluted methane jet into a crossflow of oxygen (flame lies inside), in order to gauge the influence of changing the location of heat release with respect to the shear layer. These two configurations lead to significant differences in the spatial orientation of shear-heat release interactions and how the vorticity interacts with regions on the other side of the jet. The results demonstrate that the presence of heat release in the near field has a suppressive effect on shear layer growth as well as the development of the counter-rotating vortex pair (CVP) and this effect is amplified in the case where the flame is moved inside the shear layer.

4:05PM A15.00006 Lagrangian Coherent Structures (LCS) in crossflow jets subject to very strong Favorable Pressure Gradient (FPG)¹, GERMAN SALTAR RIVERA, CHRISTIAN LAGARES, GUILLERMO ARAYA, University of Puerto Rico - Mayaguez — Incompressible jets transversely issuing into a spatially-developing turbulent boundary layer is one of the most challenging types of three dimensional flows due to its thermal-fluid complexity and technological applications: film cooling of turbine blades, fuel injection, thrust vector control, chimney plumes, among others. Complex interactions between the jet and the crossflow create a variety of coherent structures which govern the flow’s transport properties, most notably, the counter-rotating vortex pair (CVP). The CVP’s influence in the thermal transport of a turbulent round jet in a crossflow with a strong FPG has been previously studied by Quinones & Araya (2017). The FPG exhibited a damping effect on the CVP wake development and a wall-normal stretch on its geometry. To expand upon this work, we conduct Direct Numerical Simulation (DNS) at different jet velocity ratios (i.e., VR = 0.5, 1 and 2) and make use of the Finite-Time Lyapunov Exponent (FTLE) as well as the Finite-Space Lyapunov Exponent (FSLE) to detect and evaluate LCS. The main purpose is to shed light of the combined effect of crossflow-jet and strong FPG on passive scalar transport.

Saturday, November 23, 2019 3:00PM - 4:31PM – Session A16 Advances in LES Modeling I 4c3 - Sanjeeb Bose, Stanford

3:00PM A16.00001 Towards large-eddy simulation of maneuvering vehicles using an unstructured overset grid method¹, NICK MORSE, WYATT HORNE, KRISHNAN MAHESH, University of Minnesota — We discuss the development of large-eddy simulation (LES) capability towards the simulation of maneuvering vehicles using the novel unstructured overset numerical algorithm developed by Horne and Mahesh [J. Comput. Phys. (2019) 376:585-596]. This method addresses the discrete conservation and scaling challenges of overset methodologies and allows for simulation of flows around complex moving bodies undergoing six degree-of-freedom (6 DOF) motion. We discuss the application of this method to two problems of interest. First, simulations are performed of flow over an axisymmetric body of revolution with comparison to experimental data and previous LES studies. Second, a controller is integrated with the overset methods 6 DOF solver to control the motion of the body in external fluid flow. Validation examples and applications are discussed.

3:13PM A16.00002 Wall-modeled LES of rough-wall flows using the amplitude modulation framework¹, SICONG WU, University of Illinois at Urbana-Champaign, KENNETH CHRISTENSEN, University of Notre Dame, PAUL FISCHER, University of Illinois at Urbana-Champaign, CARLOS PANTANO, University of Southern California — The framework of amplitude modulation (AM) is ideally suited for the wall-modeled LES of turbulent boundary layer flows since the only model input is the large-scale flow information in the outer resolved region by LES. Adapted from the predictive models pioneered by Mathis et al. (2011) and Mathis et al. (2013), wall-boundary conditions (velocities and wall shear stresses) at the first wall-normal grid point maintained in the log region are proposed for turbulent flow over rough walls, where the model coefficients are calibrated from available DNS and experiments and the universal signals are generated using synthetic turbulence of specified energy spectrum and Reynolds stresses. Statistics including the mean velocity, turbulent stresses and dissipation will be collected and compared to the reference data.

3:26PM A16.00003 Dynamic slip wall model for compressible turbulent flows¹, KEVIN GRIFFIN, Center for Turbulence Research, Stanford University, SANJEEBBOSE, Cascade Technologies, Inc., PARVIZ MOIN, Center for Turbulence Research, Stanford University — The dynamic slip wall model (Bose and Park, ARFM, 2018) for LES is extended to compressible flows. Slip boundary conditions are used for velocity and temperature, and the slip lengths are computed dynamically. The slip wall boundary condition is a new paradigm for wall modeled LES that does not rely on RANS modeling used in traditional wall modeled LES. In this presentation, the slip wall model is applied to a transonic, transitional turbine inlet guide vane (Arts and de Rouvroit, ASME J. Turbomachinery, 1992), using unstructured CharLES code. The slip wall model is applied uniformly to the laminar, transitional, and turbulent sections of the flow. No a priori knowledge of the transition location is needed. The heat transfer on the blade is well predicted using the slip wall model. The use of a slip wall model in the under-resolved laminar section is motivated with an analysis of how slip improves the numerical prediction of the self-similar Falkner-Skan equation with limited resolution.

3:39PM A16.00004 Numerical Dissipation and Subgrid-scale Modeling for High-order DG Schemes, DAVID FLAD, USRA, SCOTT MURMAN, NASA Ames Research Center — Using high-order discontinuous-Galerkin (DG) methods for large-eddy simulation (LES) continues to increase in popularity. The methods are often favored over high-order finite-difference schemes due to their geometrical flexibility, dense numerical operators, and minimal inter-processor communication. Often the methods are used with no explicit LES model added, relying on the inherent dissipation of the method to account for unresolved stresses, i.e. implicit LES. In order to obtain nonlinear stability polynomial de-aliasing (“exact” numerical quadrature) is frequently applied. In the current work, we analyze the quality of LES for an high-order implicit time discretization and various high-order spatial discretizations, with a focus on the different effects of inherent numerical dissipation of the schemes. Dissipation-free spatial operators are used to separate modeling terms and discretization errors. The suitability and limitation for high Reynolds number turbulent flows is analyzed and compared to results when adding an explicit subgrid-scale model, such as the Smagorinsky model. Results are presented for decaying homogeneous isotropic turbulence and wall-bounded channel flow.

3:52PM A16.00005 SGS Model Based on Removal of Small-Scale Energy Production through Nonlinear Interactions1, JULIAN DOMARADZKI, GUANGRUI SUN, University of Southern California — Nonlinear dispersive SGS models are not sufficiently dissipative in actual LES. In this work a new nonlinear model is proposed to remove the unphysical energy accumulation near the LES cutoff. The model is derived based on the analysis of the nonlinear energy transfer among scales of different size and can be regarded as a direct removal of the energy production in targeted regions. We compare the present model with other nonlinear models and regularization techniques both theoretically and numerically. We show that through the removal of energy production in a targeted region of scales in the vicinity of the LES cutoff the new model is able to provide sufficient SGS dissipation in actual LES. The scale separation is facilitated by a smooth low-pass filter, which becomes increasingly more active for smaller resolved scales. Since the filter already takes grid size into account, the model is found to consistently produce accurate results in a posteriori tests in LES of turbulent channel flow at various grid resolutions and Reynolds numbers. Our results demonstrate that the energy pileup at small resolved scales in insufficiently dissipative LES can be removed by a simple modification of the nonlinear term without a need for extra dissipative terms such as an eddy-velocity model.

1Supported by NSF

4:05PM A16.00006 An algebraic non-equilibrium wall-stress model for LES by analytically integrating the TBLE1, KAZUHIKO SUGA, TOMOKI SAKAMOTO, YUSUKE KUWATA, Osaka Prefecture University — An algebraic non-equilibrium wall-stress model for large eddy simulation is proposed. The ordinary differential equation (ODE) of the thin-layer approximated momentum equation including the temporal, convection, and pressure gradient terms is considered to form the wall-stress model. Applying the ideas of the analytical wall function for Reynolds averaged turbulence models, the profile of the sub-grid-scale eddy viscosity inside the wall adjacent cells is modeled as two-segment piecewise linear variations. This simplification makes it possible to analytically integrate the ODE near the wall to algebraically give the wall shear stress as the wall boundary condition for the momentum equation. By applying such an integration to the wall-normal velocity component, the methodology to avoid the log-layer mismatch is also proposed. Coupled with the standard Smagorinsky model, the proposed model shows good performance in turbulent channel flows at Re = 1000 - 5000 irrespective of the grid resolutions. The proposed model is also confirmed to be superior to the traditional equilibrium wall stress model in a turbulent backward-facing step flow.

4:18PM A16.00007 Fractional gradient based subgrid-scale models of turbulence1, PATRICIO CLARK DI LEONI, TAMER ZAKI, Johns Hopkins University, GEORGE KARNIAKAKIS, Brown University, CHARLES MENEVEAU, Johns Hopkins University — In large eddy simulations, the effects of the unresolved scales are encapsulated in the turbulence subgrid-scale model. Whether the model can reproduce the correct two-point correlations in the filtered velocity field in LES is governed by its Karman-Howarth equation, and specifically whether the model correctly captures the two-point correlation functions between the stresses and the filtered strain-rates. Inspired by this statistical necessary condition, we develop a model that takes into account non-local effects by using fractional derivatives, and evaluate its performance using data from the Johns Hopkins Database (JHTDB). Starting from direct numerical simulation data of homogeneous isotropic turbulence and channel flows, we filter the data to separate the small and large scales, and calculate the two-point stress-strain rate correlations for the exact case and for models (a-priori) with different fractional orders. We observe that the Smagorinsky model based on standard gradients fails to produce the long range correlations observed in the exact case, while the fractional-gradient models capture the longer tails of the true correlations. As one approaches the wall in channel flow, more complex, highly anisotropic behavior is found.

Saturday, November 23, 2019 3:00PM - 4:31PM — Session A17 Energy Harvesting: General 4c4 - Brian Polagye, University of Washington

3:00PM A17.00001 Reliability Study of a Fully-Passive Oscillating-Foil Turbine Concept1, WALTFRID LEE, DYLAN IVerson, University of Victoria, GUY DUMAS, Laval University, PETER OSHKAI, University of Victoria — A self-sustained fully-passive flapping-foil hydrokinetic turbine prototype subjected to water flow at the Reynolds number of 21000 in a water channel. The prototype was exposed to three distinct types of flow disturbances: symmetric vortices shed from an oscillating foil placed upstream of the test foil, boundary layer tripping by distributed roughness on the side face of the foil, and freestream turbulence introduced via a fractal grid turbulence generator. The potential of power extraction of the foil undergoing elastically constrained oscillations in heave and pitch under these nonideal, unsteady flow conditions was quantified by implementing an eddy current brake. When placed in the wake of an upstream oscillating foil, the fully-passive turbine was sensitive to the frequency of the shed vortices in the incoming flow. An overall increase in power extraction was observed when the turbine was subjected to the high freestream turbulence and when the surface roughness was applied.

3:13PM A17.00002 Vortex Trajectory of High Pitch-High Heave Oscillating Hydrofoils, BERNARDO LUIZ ROCHA RIBEIRO, JENNIFER FRANCK, University of Wisconsin, Madison — Oscillating pitching and heaving foils have been shown to be an efficient mechanism for harvesting hydrokinetic energy. Due to the high pitch and heave amplitudes required for energy production, oscillating foils produce a wake of coherent vortices that interact with downstream foils in array configurations. In order to better predict the vortex-foil interactions, the formation and trajectory of the primary leading edge vortex (LEV) is explored computationally. The hydrofoil kinematics are varied with reduced frequencies of \( \Omega_c/U_c = 0.1 \) and 0.15, with heave amplitudes of 0.5—2c and pitch amplitudes of 65°—85°. The downstream position and timing of the LEV is relatively independent of Reynolds number, but it is strongly influenced by the kinematics. Differences in flapping frequency produce two different LEV trajectory patterns due to changes in the LEV structure during the heave stroke. At the higher frequency the LEV remains attached longer and thus has a lower convective speed in the wake. As the pitch amplitude is increased the LEV size and its trajectory’s vertical distance increase linearly, however as the heave amplitude is increased the maximum vertical distance traveled by the LEV saturates non-linearly.

3:26PM A17.00003 Experimental and Analytical Limitations of Blockage Corrections1, HANNAH ROSS, BRIAN POLAGYE, University of Washington — Flow confinement can significantly impact the performance of wind and water turbines. These effects become appreciable if the blockage ratio, defined as the turbine’s projected area divided by the cross-sectional area of the tunnel or channel, is larger than 5–10%. Due to experimental and computational limitations, studies are often conducted at blockage ratios that exceed this threshold. To estimate performance in unconfined conditions, analytical corrections can be applied to data collected in confined flow. Multiple analytical corrections based on linear momentum theory have been proposed in the archival literature. A previous study by the authors explored the effectiveness of these corrections when applied to experimental data from an axial-flow turbine and a cross-flow turbine. We found that, overall, estimates for unconfined thrust coefficients were more accurate than estimates for unconfined power coefficients. Here, we explore possible causes for this discrepancy in performance. Specifically, we examine the influence that Reynolds dependence and the assumptions that underpin linear momentum theory have on the effectiveness of the power coefficient corrections.

3:39PM A17.00004 Experimental evidence for coupled-mode flutter in a two-meter long parked wind turbine blade, PIETER BOERSMA, BRIDGET BENNER, TODD CURRIER, YAHYA MODARRES-SADEGHI, University of Massachusetts Amherst — We have conducted a series of experiments on a relatively large-scale wind turbine blade and observed coupled-mode flutter. Theoretical studies predict that the future wind turbine blades are susceptible to coupled-mode flutter. Experimental validation of this prediction is difficult, due to the inherent complications in conducting experimental work on structures that could become unstable due to flutter. We have built a relatively large model of the NREL 5 MW blade from a flexible plastic. The blade was 2 meters long and was comprised of two 0.5 cm-thick shells bonded together such that the torsional natural frequency and the flapwise natural frequencies had a similar ratio to those in the full-scale. This was important, because the theoretical predictions suggest that the third flapwise and the first torsional natural frequencies coalesce into a coupled mode flutter mode. Our experimental results clearly show this coalescence and the resulting modal oscillations in which a combined flapwise and torsional motion is observed.

3:52PM A17.00005 Dynamics and coupling of inertial particles on the wake recovery and flow entrainment of a wind turbine, SARAH SMITH, KRISTIN TRAVIS, Department of Mechanical and Materials Engineering, Portland State University, HENDA DJERIDI, MARTIN OBLIGADO, LEGI - Laboratoire des coulants Géophysiques et Industriels, RAL BAYON CAL, Department of Mechanical and Materials Engineering, Portland State University — Impacting particles such as rain, dust, and other debris can have devastating structural effects on wind turbines, but little is known about the interaction of such debris within turbine wakes. This study aims to characterize the behavior of inertial particles within the axisymmetric turbulent wake of a wind turbine and the resulting effects on wake recovery. Here a model wind turbine is subjected to varied two-phase inflow conditions with wind as the carrier fluid (\( Re_L = 17.7 \times 10^3 - 39.3 \times 10^4 \)) and polydisperse water droplets (averaging 60 micrometers in diameter) at varied concentrations (\( \phi_v = 9.7 \times 10^{-6} - 2.6 \times 10^{-5} \)). Phase doppler interferometry (PDI) and particle image velocimetry (PIV) were employed at multiple downstream locations, centered with respect to turbine hub height. Analysis considers energy and particle size distribution within the wake focusing on particle entrainment, settling velocity, and preferential concentration. Near wake statistics show similarities to those of turbines in single-phase flows, and show persisting velocity deficits at least as far as 9.5 rotor diameters downstream. Complex particle behavior is evident in the near wake region where small particles are captured within tip vortices and central wake regions.

4:05PM A17.00006 Wind Turbine Icing Physics and A Novel Strategy for Wind Turbine Icing Mitigation1, LINYUE GAO, HUI HU, Iowa State University — Wind turbine icing represents the most significant threat to the integrity of wind turbines in cold weather. By leveraging the Icing Research Tunnel available at Iowa State University (ISU-IRT), an experimental study was conducted to elucidate the underlying physics of the important micro-physical processes pertinent to wind turbine phenomena and explore novel anti-/de-icing strategies for wind turbine icing mitigation. A suite of advanced flow diagnostic techniques, which include molecular tagging velocimetry and thermometry (MTV&T), digital image projection (DIP), and infrared (IR) imaging thermometry, were developed and applied to quantify the transient behavior of wind-driven surface water film/ripariot flows, unstable heat transfer and dynamic ice accreting process over the surfaces of wind turbine blade models. A novel, hybrid anti-/de-icing strategy that combines minimized electro-heating at the blade leading edge and an ice-phobic coating to cover the blade surface was developed for wind turbine icing mitigation. In comparison to the conventional strategy to brutally heating the mass blade surface to keep the blade ice free, the hybrid strategy was demonstrated to be able to achieve the same anti-/de-icing performance with substantially less power consumption (i.e., up to 90% power saving).

4:18PM A17.00007 Reduced-order transport models for energy and the environment
ZHONG ZHENG, Tsinghua-Sichuan Energy Research Institute — We present recent developments on reduced-order modelling and its applications to energy and environmental processes, such as geological CO₂ sequestration and hydraulic fracturing, which is related to the application of energy resource recovery, such as shale gas recovery. In particular, we introduce a series of gravity current models, which describe the spreading and draining dynamics of supercritical CO₂ that is injected into a saline aquifer, for example. In many situations we consider here, self-similar solutions are available to describe some of the interesting dynamics, considering the effects of buoyancy, surface tension, and heterogeneity, for example. We next introduce a series of experimental work that is related to the dynamics of hydraulic fracturing. Model viscous fluids and elastic solids have been employed for the laboratory-scale experiments, and scaling argument has been performed to describe the spatial and temporal evolution of the hydraulic fractures and some of the parametric dependence. We also point out several future research directions and hopefully bring in more interests on this topic.

Saturday, November 23, 2019 3:00PM - 4:31PM — Session A18 Turbulence Measurements

3:00PM A18.00001 Resolvent-mode-based Reconstruction of Wall-bounded Turbulent Flows From Non-time-resolved PIV Measurements¹
MENGYING WANG, MAZIAR HEMATI, University of Minnesota, MITUL LUHAR, University of Southern California — Turbulent flows are characterized by broadband spatio-temporal fluctuations, which makes the acquisition of fully-resolved velocity measurements challenging. The goal of this study is to use a physics-based model—projecting the velocity field onto resolvent modes—to reconstruct velocity field from non-time resolved 2D PIV measurements in turbulent channel flow. The resolvent modes are generated via a gain-based decomposition of the governing equations, ensuring physical consistency. A large database of resolvent modes is generated. The Forward Regression with Orthogonal Least Squares algorithm is then used to identify the dominant resolvent modes and to calibrate their amplitude and phase. After calibration, the velocity field can be reconstructed at arbitrary spatiotemporal resolution using the weighted resolvent modes. The weighted resolvent modes also enable estimation of out-of-plane components of velocity and pressure. For proof-of-concept tests of this method, we use DNS data of turbulent channel flow from the Johns Hopkins Turbulence Database. Reconstruction error is quantified and compared with previous studies using Rapid Distortion Theory and Taylor's Hypothesis for reconstruction.

3:13PM A18.00002 An eigen-ensemble-variational algorithm for identifying scalar sources from remote measurements in turbulent environments¹
QI WANG, TAMER ZAKI, Johns Hopkins University — The ability to identify the location and intensity of a scalar source in turbulent environment from remote measurements is obfuscated by the stochasticity of turbulent eddies and by diffusion. An algorithm is proposed to solve this inverse problem, which relies on estimating the left and right singular vectors of the scalar impulse-response system, or its eigen-sources and eigen-measurements. The projection of the true source onto an eigen-source is proportional to the projection of the sensor signal onto the corresponding eigen-measurement, and the proportionality is given by the singular value. When only the sensor signal is available, the unknown source is identified by requiring that it accurately reproduces this proportionality. A pre-requisite of the algorithm is knowledge of the eigen-spectrum of the system, which can be available from historical data or approximated using proper orthogonal decomposition of the observation matrix from an ensemble of trial sources. We demonstrate that using only five ensemble members, the source location and intensity are predicted with less than 10% error, and we quantify the effect of sensor noise. Furthermore, the algorithm utilizes forward simulations only and can be easily adopted with expanding time horizon of measurement.

3:26PM A18.00003 On the dynamics of Reynolds stresses in the tip region of axial turbomachines¹
HUANG CHEN, The Johns Hopkins University, YUANCHAO LI, DAVID TAN, JOSEPH KATZ, Johns Hopkins University — Experiments examining the flow in the tip regions of axial turbomachines have been performed in a refractive index matched facility, enabling unobstructed optical access. Stereo PIV measurements in closely spaced planes provide high-resolution 3D distributions of the strain, pressure diffusion and velocity–pressure gradient tensor in the Reynolds stress transport equation in canonical turbulent flows is of critical importance for calibrating and improving turbulence models for RANS (Reynolds-Averaged Navier Stokes) based flow simulation. Recent work of Liu and Katz (2018) based on planar-PIV shows the complex nature of the pressure related terms and their substantial impact on the dynamics of turbulence transport throughout a shear layer flow past an open cavity. They also demonstrate the need for a full three-dimensional characterization of the pressure-related turbulence transport terms around the cavity trailing corner. To address this need, time-resolved tomographic PIV measurements of a turbulent shear layer flow past an open cavity is being carried out. The curl-free property of the pressure gradient is used to control the quality of the measured pressure gradient, and the continuity equation is used to control the quality of the velocity measurement. The incoming flow quality is fully characterized so as to facilitate CFD simulation. Detailed velocity and Reynolds stress profiles and turbulence spectrum at selected locations, as well as preliminary tom-PIV data of the flow field just above the cavity trailing corner, will be presented.

3:39PM A18.00004 Time-resolved tomographic PIV measurements of a turbulent shear layer flow past an open cavity¹
JOSE MORETO, San Diego State University; University of California, San Diego, XIAOFENG LIU, San Diego State University — Characterization of the pressure-related turbulence terms including pressure–rate-of-strain, pressure diffusion and velocity–pressure-gradient tensor in the Reynolds stress transport equation in canonical turbulent flows is of critical importance for calibrating and improving turbulence models for RANS (Reynolds-Averaged Navier Stokes) based flow simulation. Recent work of Liu and Katz (2018) based on planar-PIV shows the complex nature of the pressure related terms and their substantial impact on the dynamics of turbulence transport throughout a shear layer flow past an open cavity. They also demonstrate the need for a full three-dimensional characterization of the pressure-related turbulence transport terms around the cavity trailing corner. To address this need, time-resolved tomographic PIV measurements of the 3D pressure-related terms in the Reynolds stress transport budget for a turbulent shear layer past a cavity is being carried out. The curl-free property of the pressure gradient is used to control the quality of the measured pressure gradient, and the continuity equation is used to control the quality of the velocity measurement. The incoming flow quality is fully characterized so as to facilitate CFD simulation. Detailed velocity and Reynolds stress profiles and turbulence spectrum at selected locations, as well as preliminary tom-PIV data of the flow field just above the cavity trailing corner, will be presented.

3:52PM A18.00005 Automatic identification and characterization of bursting periods in a turbulent velocity field1, RONI HILEL GOLDSHMIID, DAN LIBERZON, Technion - Israel Institute of Technology, T-SAIL TEAM — A new automatic method for accurate detection of bursting periods in single-point velocity field records is presented. Identification of bursting periods is made by locating an instantaneous increase in the normalized “instantaneous” TKE dissipation rate, obtained using moving window averaging. Use of the record rms and average values for normalization eliminate the need to define flow specific thresholds, and hence decouples burst identification from the generation mechanism. This potentially makes the method universally applicable across various types of turbulent flows. The method performance is examined using a dataset of buoyancy driven turbulent boundary layer flow. Turbulent statistics of the identified non-bursting periods show distinguished similarity to those expected in canonical turbulence, while the identified bursting period statistics differ significantly. To examine the bursting period generation mechanism, statistical findings of temperature fluctuations are examined, and additional tests are provided to assist in identification of the generation mechanism. Examination of the flow field scalar variations in connection with turbulent bursting periods can assist in further understanding of bursting generation and scalar transfer processes.

4:05PM A18.00006 Lagrangian acceleration time scales in anisotropic turbulence1, ROMAIN VOLK, Univ Lyon, Ens de Lyon, Univ Claude Bernard, CNRS, Laboratoire de Physique, Lyon, France, PETER HUCK, NATHANAEL MACHICOANE, University of Washington - Department of Mechanical Engineering, Seattle, WA, USA — We present experimental Lagrangian measurements of tracer particle acceleration auto-correlation functions in an anisotropic and inhomogeneous flow spanning the typical range of experimentally accessible Reynolds numbers. The large scale forcing of the flow creates a stagnation point topology where straininduced motion governs the anisotropic velocity and acceleration fluctuations. We show that the time scales of the acceleration components remain anisotropic even at high Reynolds numbers and that they are related to the dissipative time scale by the Lagrangian structure function scaling constants \( C_0 \) and \( a_0 \). The scaling relation proposed herein is supported by observations using experimental Lagrangian trajectory data sets and analytical calculations using a jointly-Gaussian two-time stochastic model. Examination of acceleration spectra shows that acceleration fluctuations become isotropic in the dissipative range which suggests that the acceleration time scale is not only determined by small scales, but also by large and anisotropic scales whose contributions are substantial, even in the high Reynolds number limit.

4:18PM A18.00007 Inter-scale energy budget in a von Kármán mixing tank, ANNA N. KNUTSEN1, PAWEL BAJ, NICHOLAS A. WORTH, JAMES R. DAWSON, Norwegian University of Science and Technology, JOHN M. LAWSON, University of Southampton, EBERHARD BODENSCCHATZ, Max Planck Institute of Dynamics and Self-Organisation — The inter-scale energy budget in the center region of a von Kármán mixing tank has been investigated based on fully resolved measurement data from volumetric and stereo PIV experiments at \( Re_L = 199 \). The Kármán-Howarth equation generalized for non-isotropic, inhomogeneous turbulence (sometimes referred to as the Kármán-Howarth-Monin-Hill equation) is used to map the full energy transfer, and determine the importance of the different mechanisms transporting energy. The results show that the mean flow, despite its small magnitude relative to the turbulent fluctuations, plays a significant role in the local inter-scale energy transfer. This result stands out from similar investigations of other types of flows, where the mean flow has been found to have a negligible role in transporting energy across scales. This large contribution is caused by the strong gradients in all directions of the mean flow, which is a special feature of the von Kármán flow. The isotropy of the various terms is also evaluated, and strong local variations of the different terms in scale space are observed even down to very small separations, highlighting the importance of using planar or volumetric data when energy transfer is studied.

Saturday, November 23, 2019 3:00PM - 4:31PM – Session A19 Advanced Turbulence Models I 401 - Todd Oliver, University of Texas, Austin

3:00PM A19.00001 Physics-informed deep neural networks applied to scalar subgrid flux modeling in a mixed DNS/LES framework, GAVIN PORTWOOD, Los Alamos National Laboratory, MISHA CHERTIKOV, University of Arizona, BALASUBRAMANYA NAIDIGA, JUAN SÀENZ, DANIEL LIVESCU, Los Alamos National Laboratory — The application of artificial neural networks (ANNs) to turbulence closure has been an emergent and active area of research in recent years due to the success of such data-driven methods in fields of computer vision, natural language processing, and other industrial and scientific disciplines. In this research, we apply ANNs to spatio-temporal dynamic modeling of the subgrid passive scalar flux as it relates to large-eddy simulations (LESs). By training on direct numerical simulations (DNSs) of homogeneous isotropic turbulence coupled to a passive scalar, we optimize ANNs to predict the subgrid scalar flux as a function of resolved-scale features. Trained models are then implemented in simulation and evaluated with a-posteriori analysis. In these simulations, filtered scalar advection is coupled to explicitly filtered and statistically-stationary turbulence such that scalar dynamics have no dependence on potentially inaccurate subgrid stress models. By analysis with single- and multi-point statistics, we demonstrate that the data-driven models compete, and often out-perform, properly optimized canonical models. We suggest that this simulation framework may serve as a simplified closure testbed for the investigation and evaluation of data-driven turbulence closures.

3:13PM A19.00002 Fractional physical-inform neural networks (fPINNs) for turbulent flows1, FANGYING SONG, GUOFEI PANG, Division of Applied Mathematics, Brown University, CHARLES MENEVEAU, Mechanical Engineering, Johns Hopkins University, GEORGE KARNIADAKIS, Division of Applied Mathematics, Brown University — We employ fractional operators in conjunction with physics-informed neural networks (PINNs) to discover new governing equations for modeling and simulating the Reynolds stresses in the Reynolds Averaged Navier-Stokes equations (RANS) for wall-bounded turbulent flows at high Reynolds number. In particular, we develop a simple one-dimensional model for fully-developed wall-turbulence that involves a fractional operator with fractional order that varies with the distance from the wall. We use available DNS data bases to infer the function that describes the fractional order, which has an integer value at the wall and decays monotonically to an asymptotic value at the centerline. We show that this function is universal upon re-scaling and hence it can be used to predict the mean velocity profile at all Reynolds numbers. We also extend the fractional RANS for fully-developed turbulent channel flow to a turbulent boundary layer and infer the fractional order in the wake region.

3:26PM A19.00003 Wall-modeled large-eddy simulation of a turbulent channel flow based on artificial neural network1, YOUNG MO LEE, UNIST, JUNGIL LEE, Ajou University, JAE HWA LEE, UNIST – Because the computational cost of large-eddy simulation (LES) in the near-wall region of wall-bounded flows is proportional to approximately square of the friction Reynolds number ($Re_\tau$), utilizing wall-modeled LES (WMLES) is promising to simulate a turbulent flow at sufficiently high Reynolds number with a reasonable cost. The most widely used wall model is an equilibrium stress model (i.e., wall-stress model) based on the momentum conservation. However, this method still needs to improve the accuracy and applicability for complex flows (e.g., swirled or separated flow) due to the limitations of the equilibrium assumption. In the present study, we employ an artificial neural network (ANN) to obtain information of the wall shear stress for WMLES. The proposed method shows good prediction on the mean velocity and Reynolds stress profiles compared to previous models in a turbulent channel flow in the range of the friction Reynolds numbers ($395 < Re_\tau < 5200$), even though the turbulent statistics at untrained Reynolds numbers are predicted.

3:39PM A19.00004 Zonal Turbulence Modeling via Decision Trees..1, RACHEET MATAI, Geminus.AI, PAUL DURBIN, Iowa State University – The idea of a zonal model is a given model, but with its coefficients varying in different regions of a flow. That idea suggests using a form of classifier to identify zones. The bag-of-trees algorithm has been used to devise a zonal k-omega model. The training data are optimized, coefficient discrepancy fields, obtained by the method of Duraisamy, et al, 2015. The optimization is done with LES data as the target for flow over a circular arc bump. The discrepancy data are binned, with each bin assigned a particular range of values. The zones are parameterized by training the machine learning model with a local feature set. The features are coordinate invariant flow parameters. The classification that is derived by ML is close to associating zones with adverse and favorable pressure gradients. The correction produced by the machine learning algorithm is self-consistent; i.e. once the solution converges, the zones remain fixed.

1Funded by National Science Foundation Grant No. 1507928 and NASA grant NNX15AN98A. We are grateful for Prof. K. Duraisamy for providing data on optimized coefficients.

3:52PM A19.00005 Fractional-Order LES Subgrid-Scale Modeling: Theory and Numerics1, MEHDI SAMIEE, ALI AKHAVAN-SAFAEI, MOHSEN ZAYERNOURI, Michigan State University – Filtering the Navier-Stokes equations in the large-eddy simulation of turbulent flows inherently introduces nonlocal features in the subgrid scale fluid motion. Such long-range effects become even more pronounced when the filter- width enlarges. That urges the development of new nonlocal closure models, which respect the corresponding non-Gaussian statistics of the subgrid stochastic motions. Starting from the filtered Boltzmann equation, we model the corresponding equilibrium distribution function with a Lévy stable distribution, which leads to the proposed fractional-order modeling of subgrid-scale stresses. We approximate the filtered equilibrium distribution function with a power-law term, and we derive the corresponding fractional Laplacian, $(Δ)^α$, $α ∈ (0, 1]$, of the filtered velocity field. Finally, the introduced model undergoes a priori evaluations based on the direct numerical simulation database of forced and decaying homogeneous isotropic turbulent flows at high and moderate Reynolds numbers, respectively.

4:05PM A19.00006 Motivation and development of the time-averaged active model-splitting hybrid RANS/LES1, SIGFRIED HAERING, Argonne National Laboratory, TODD OLIVER, Oden Institute for Computational Engineering and Sciences, RAMESH BALAKRISHNAN, Argonne National Laboratory, ROBERT MOSER, Oden Institute for Computational Engineering and Sciences — We discuss motivation and development of the time-averaged active model-split (TAMS) hybrid RANS/LES approach. TAMS has been specifically constructed to overcome challenges associated with existing hybrid approaches related to LES/RANS blending techniques and inconsistencies between the resolved and modeled turbulence. Core to TAMS is a hybridization strategy in which the RANS and LES components act through separate models formulated using the mean and fluctuating velocity, respectively, as approximated by time averaging over the local turbulent timescales. Justification for this splitting strategy is discussed based on true subgrid terms from filtered DNS and simple LEVM arguments. Multiple validation cases are used to demonstrate the potential of the method.

4:18PM A19.00007 Numerically measured scale-dependent eddy viscosity in homogeneous isotropic turbulence, YASAMAN SHIRIAN, ALI MANI, Stanford University — In the present work, we report the directly measured eddy viscosity in incompressible homogeneous isotropic turbulence using the macroscopic forcing method. Our results provide a scale-dependent eddy viscosity; specifically, in the low-wavenumber-limit, eddy viscosity is a constant, while in the high-wavenumber limit, it becomes inversely proportional to the wavenumber. Our results present a contrast to the previously reported eddy diffusivity via renormalization group theories (Yakhot and Smith 1992), this difference is attributed to proper quantification of transport at small scales by large-eddies in the present study. We also report the scale-dependent turbulent Schmidt number as well as collapse of the measured eddy-viscosity operator with increase of flow Reynolds number. Supported by DOE

Saturday, November 23, 2019 3:00PM - 4:31PM — Session A20 Geophysical Fluid Dynamics General I 602 - Jerome Neufeld, Cambridge
3:00PM A20.00001 Formulation and implementation of free-slip boundary condition on a deformed domain in the context of continuous Galerkin high-order element-based discretization. 1, THEODOROS DIAMANTOPOULOS, PETER DIAMESSIS, Cornell University, MAREK STASTNA, University of Waterloo — The free-slip condition is a convenient choice of boundary condition (BC) used in the simulation of stratified flows to circumvent the resolution of fine-scale no-slip-driven bottom boundary layers when numerically solving the incompressible Navier-Stokes equations (INS). The nodal spectral element method is a commonly used strategy in the discretization of the INS where the free-slip condition arises as a natural BC from the integration-by-parts of the viscous term in the INS. In the context of a deformed domain, the tangential component of the force associated with the free-slip condition, couples the Cartesian velocity components leading to a larger system of equations for the calculation of the velocity field. One approach to mitigate this complexity is to impose a pseudo-traction BC, where each velocity component can be solved for independently. Effectively, the velocity components can be treated as scalar quantities allowing the use of the same computational machinery as for the calculation of the density and the pressure. In a series of test problems, which include the propagation of an internal solitary wave, the effective numerical drag produced by the pseudo-traction BC will be quantified thereby enabling the assessment of the accuracy of the pseudo-traction approach.

1 NSF-OCE 1634257

3:13PM A20.00002 Role of aeolian hysteresis and secondary turbulence in dust entrainment over arid landscapes, SANTOSH RANA, WILLIAM ANDERSON, UT Dallas — Saltation, the wind-blown hopping motion of sand particles, plays an effective role in dust eruption from the sediment bed. Low and high momentum regions appear as long streaks in atmospheric turbulence. Positive and negative vertical velocity are associated with low and high momentum regions respectively. High momentum regions initiate saltation when the fluid velocity exceeds the fluid threshold value and saltation continues till the fluid velocity drops below the impact threshold value. This phenomenon is called hysteresis or the lag between the initiation and cessation of saltation. Saltation occurs during this hysteresis period. The sweeping motion and the negative vertical velocity of the high momentum regions do not allow entrainment of the dust released during saltation. However, the positive vertical velocity associated with the low momentum region picks up the dust. A conditional averaging method is employed to study this paradox as two modes of dust entrainment. In the primary mode, the dust released by the saltating particles of the high momentum region is entrained by the neighboring low momentum region. In the secondary mode, dust released due to saltation by a very recent high momentum region is entrained by a closely following low momentum region in the flow direction. Here, we explain how dust exposed to the low momentum region as a result of hysteresis gets entrained by two modes of transport. The methodology explained here is applicable to both earth and mars conditions.

3:26PM A20.00003 Revisiting eddy diffusivity models in geophysical boundary layers, TOMAS CHOR, JAMES MCMILLIANS, MARCELO CHAMECKI, University of California, Los Angeles — Eddy diffusivity models have proved invaluable when modeling turbulent fluxes in many situations. However, in atmospheric and oceanic boundary layers, large-scale motions (for example convective plumes and Langmuir circulations) do not conform to the usual assumptions necessary for their application. This has prompted the creation of several ad-hoc models, each designed to work under rather specific conditions, and each of them often failing to work well outside their intended operating area. In this work we present an alternative unifying solution that estimates the total eddy diffusivity without a priori assumptions about its shape or scaling. The approach is based on the fact that the eddy diffusivity should depend only on the flow, which we use as a basis for an optimization procedure that uses Large-Eddy simulation data. The result of our approach is that most of the fluxes are modelled with an eddy diffusivity, while the rest (which depends on specific sources of scalars and is attributed to large scale motions) is modelled as non-dissipative processes. We present an approach of our proposed model to the classic case of a convective boundary layer and show that we are able to predict the heat flux from quantities measured using passive tracers.

3:39PM A20.00004 Semi-Empirical Models of Surface Pressure in the Planetary Boundary Layer in terms of Second-Order Structure of Atmospheric Turbulence, GREGORY LYONS, U.S. Army Engineer Research And Development Center, Construction Engineering Research Laboratory, CARL HART, U.S. Army Engineer Research And Development Center, Cold Regions Research and Engineering Laboratory — The fluctuations in surface pressure beneath turbulent boundary layers have long been of interest due to the aerodynamic noise and structural vibrations they induce. In the planetary boundary layer, analogous fluctuations at the ground surface contribute to instrument noise directly as static pressure, recorded by micrometers and microphones, and indirectly as ground motion, detected by seismographs and geophones. It is hypothesized that the fast (i.e. linear) term of the pressure Poisson equation make the principal contribution to surface fluctuations, so that only second-order structure of the inhomogeneous velocity field is necessary for modeling of second-order pressure statistics. The mirror flow model due to Kraichnan and rapid-distortion theory models proposed by Mann, which both derive inhomogeneous turbulence from initially homogeneous fields, are used to produce semi-empirical models of the surface pressure wavenumber spectrum. With an effective convection velocity, frequency pressure spectra are derived and contrasted. Using meteorological observations from a recent experiment, model parameters are estimated from velocity spectra, and the resultant pressure spectral models are compared with measurements from flush-mounted pressure sensors.

3:52PM A20.00005 The poroelastic aquifer: river flux response to solid Earth tidal forcing, JEROME NEUFELD, University of Cambridge, ERIC LAJEUNESSE, OLIVIER DEVAUCHELLE, Institut de Physique du Globe de Paris — The water flux through rivers is chieflly determined by the intermittent charging of groundwater in laterally extensive shallow aquifers by rainfall and drawdown by seepage to the river bank. Here we show that the pattern of drawdown is modulated by the small-scale forcing of shallow poroelastic aquifers by the solid Earth tides. We use a shallow poroelastic model of flow in a deformable matrix to show that the modulation of the solid stress by solid Earth tides gives rise to the observed 2-4 cm height variation in the far-field aquifer depth. This oscillatory groundwater table also drives a modulation of the water flux into the river which is apparent in long-term records of stream flux. By understanding the poroelastic response of aquifers to solid Earth tides as observed in the river flow data, we are therefore able to infer properties of distributed aquifers from readily available records of the river flow. The fluid dynamical modelling, motivated by observations at the Quick creek catchment, Guadeloupe, also demonstrates a generic framework for understanding the interaction between periodic solid stresses and fluid flow in deformable porous media.
University the interior after approximately 200 Ma, which may explain the long persistence of the Lunar dynamo on temperature, pressure and solid fraction. The resulting surface heat flux depends primarily on the temperature of the mixed interior and on explain the long timescales for crust formation. This involves convection dominated by a temperature-dependent viscosity, producing a stagnant-lid, may be more relevant to the early lunar magma ocean and explain the long timescales for crust formation. This involves convection with in a fluid whose viscosity varies by several orders of magnitude as a function of temperature and crystal fraction. The temperature scale most relevant to the convection is that over which the viscosity varies. This scale is greatly reduced during rapid changes in viscosity, such as when jamming occurs at a critical melt fraction. We consider a one-dimensional model in which the lunar magma ocean is considered as one body of convecting silicate, with a viscosity that depends strongly on temperature and solid fraction. The resulting surface heat flux depends primarily on the temperature of the mixed interior and on the hydrostatic pressure at the base of the stagnant lid. This results in an initial unstable scenario with a lid that is mostly entrained back into the interior after approximately 200 Ma, which may explain the long persistence of the Lunar dynamo.

Saturday, November 23, 2019 3:00PM - 4:31PM –
Session A21 Drops: Temperature and Marangoni Effects I

3:00PM A21.00001 Freezing-damped drop impacts , CALLUM WATSON, JEROME NEUFELD, Department of Applied Mathematics and Theoretical Physics, University of Cambridge, CHLO MICHAUT, Laboratoire de Gologie, Terre, Plante, Environnement, cole Normale Superieure de Lyon, France — Typical models of the thermal evolution of the Moon involve a solid crust growing via crystal flotation, with an underlying magma ocean then cooling by conduction through the crust. However, convection dominated by a temperature-dependent viscosity, producing a stagnant-lid, may be more relevant to the early lunar magma ocean and explain the long timescales for crust formation. This involves convection with in a fluid whose viscosity varies by several orders of magnitude as a function of temperature and crystal fraction. The temperature scale most relevant to the convection is that over which the viscosity varies. This scale is greatly reduced during rapid changes in viscosity, such as when jamming occurs at a critical melt fraction. We consider a one-dimensional model in which the lunar magma ocean is considered as one body of convecting silicate, with a viscosity that depends strongly on temperature and solid fraction. The resulting surface heat flux depends primarily on the temperature of the mixed interior and on the hydrostatic pressure at the base of the stagnant lid. This results in an initial unstable scenario with a lid that is mostly entrained back into the interior after approximately 200 Ma, which may explain the long persistence of the Lunar dynamo.

3:13PM A21.00002 Dynamics and temperature evolution during droplet impacts on cold surface , FENG WANG, MAN HU, DAOSHENG DENG, Fudan University, Shanghai, China — Droplet impacting on cold surface is significant for many practical situations in our daily life, such as anti-icing on wind turbines, aircraft and power transmission lines. By using high speed camera and thermal camera, here we report the dynamics and temperature evolution during water droplet impacts and freezes on cold metal surface. In the impact process, the maximum spread radius is found to have a 1/3 power law with the initial height, which is different from the impacting behavior at the room temperature. In the retraction process, three different morphology are indentified when changing the initial height from low to high, which is puddle, transition state and pancake. In the freezing process, the ice-water boundary and the zero degree isotherm are extracted from the high speed videos and thermal profiles. The ice-water boundary retraction speed is found to be slower than the zero degree isotherm, which indicates the subcooling freezing process.

3:26PM A21.00003 Arrested dynamics of droplets impacting icy surfaces , FARZAD AHMADI, ANDREW FUGARO, Virginia Tech, SAURABH NATH, Laboratory PMMH, ESPCI Paris, PSL Research University, France, LadHyX, Ecole polytechnique, Palaiseau, France, HYUNG-GON PARK, JONATHAN BOREYKO, Virginia Tech — We study the competition between the spreading and freezing dynamics of droplets impacting icy surfaces. Experiments were conducted on two different frosted surface configurations: planar or suspended cable. The dynamics of droplet impact were captured using a side-view high-speed camera, where the droplet was initially either at room temperature or close to the freezing temperature. For droplets spreading on the planar substrate, the advancing contact line was arrested significantly faster with decreasing surface temperature or initial droplet temperature. Droplets impacting the icy cable either detached and fell from the cable or were captured and frozen, depending upon the Weber number, surface temperature, droplet temperature, and the ratio of the droplet and cable diameters. A scaling model elucidated that the extent of droplet spreading is a balance between capillary-inertial effects and the specific cooling of the droplet toward its freezing temperature.

3:39PM A21.00004 Coalescence dynamics of a droplet on a heated pool , PANKAJ KOLHE, PAVAN KUMAR KIRAR, Indian Institute of Technology Hyderabad, India, KATHRYN ALVARENGA, Texas A&M University, KIRTI SAHU, Indian Institute of Technology Hyderabad, India — We experimentally investigated the coalescence dynamics of an ethanol drop in ethanol pool maintained at a higher temperature than the drop. The size of the impacting drop and the temperature difference between the pool and the drop are varied and their effect on the secondary droplet formation has been studied. It is observed that increasing the temperature of the liquid pool, has a non-monotonic effect on the partial coalescence phenomenon. Increasing the droplet size increases the size of the secondary drop for all values of the temperature differences considered in the present study.
3:52PM A21.00005 Evaporation of ethanol-water sessile droplet of different compositions at an elevated substrate temperature. SARAVANAN BALUSAMY, SAYAK BANERJEE, PRADEEP GURRALA, PALLAVI KATRE, KIRTI SAHU, Indian Institute of Technology Hyderabad, India — We experimentally investigate the evaporation dynamics of sessile droplets with different compositions of ethanol-water binary mixture at different substrate temperatures. At elevated substrate temperature, we observed an early spreading stage, an intermediate pinned stage and a late receding stage of evaporation. Increasing the substrate temperature decreases the lifetime of binary droplets rapidly. We found that the lifetime of the droplet exhibits a non-monotonic trend with increase in ethanol concentration in the binary mixture, which can be attributed to the non-ideal behaviour of water-ethanol binary mixtures. Interestingly, the evaporation dynamics for different compositions at high substrate temperature exhibits a self-similar trend showing a constant normalised volumetric evaporation rate for the entire evaporation process. This indicates that the evaporation dynamics of a binary droplet of a given composition at high substrate temperature is equivalent to that of another pure fluid with a higher volatility at room temperature. The evaporation rates of pure and binary droplets at different substrate temperatures are compared against a theoretical model developed for pure and binary mixture droplets. The model predictions are found to be quite satisfactory.

4:05PM A21.00006 Evaporation of ethanol-water sessile droplet on an inclined substrate at an elevated temperature. SAYAK BANERJEE, SARAVANAN BALUSAMY, PALLAVI KATRE, PRADEEP GURRALA, KIRTI SAHU, Indian Institute of Technology Hyderabad, India, PHASE CHANGE IITH COLLABORATION — We experimentally investigated the evaporation dynamics of water-ethanol binary droplets of various molar compositions on an inclined heated substrate. The substrate temperature and inclination angle are varied and the droplet behaviour are observed using a combined optical and thermal imaging techniques in a custom-made goniometer-IR camera set-up. The triple line behaviour, the contact angle and the wetting diameter evolution of the droplet, as well as thermo-solutal Marangoni wave dynamics are studied. Theoretical modelling of evaporation rates for binary-droplets on heated inclined substrates has been performed and compared against the experimental results.

4:18PM A21.00007 Residues formation on surface of heated wire after drop impact: correlation between solution drop impact dynamics and residues thickness. KYEONGMIN KIM, SANG JUN LEE, WONJONG CHOI, Korea University — Impact between solid structures and solutions essentially leaves residues on surfaces, such as calcite in water. While the impacting angle and velocity of the solution affect the formation of the residues, the temperature regime of the solid surface is another significant factor because it intrinsically manipulates the contact interfaces between liquids and solids, as well as their solubility. Herein, we report a systematic study of the residual nanomaterials after a drop impact containing carbon nanotubes (CNTs) on a heated metal wire in various temperature range. While a drop casting method for the individual droplet comprising CNTs induces the impact with 2-mm nichrome wires in diameter, a joule-heating method controls the wire temperature in 25-400 C. The phase diagram in terms of the impact velocity, wire temperature, and formation of the residues are quantitatively investigated to elucidate the correlation between the solution drop impact dynamics and the resulting CNT residue thicknesses. The fundamental understanding of the residual nanomaterials, induced by the impact between solid structures and solutions in wide temperature ranges would provide the insight for a robust design of broad engineering systems such as heat exchangers, solar power modules, and turbines.

Saturday, November 23, 2019 3:00PM - 4:31PM — Session A22 Drops: Coalescence I 604 - Sumeet Thete, Air Products

3:00PM A22.00001 Internal Flows in Impacting and Coalescing Droplets of Different Surface Tension. THOMAS C. SYKES, University of Leeds, ALFONSO A. CASTREJON-PITA, University of Oxford, J. RAFAEL CASTREJON-PITA, Queen Mary University of London, MARK C. T. WILSON, DAVID HARBOTTLE, ZINEDINE KHATIR, HARVEY M. THOMPSON, University of Leeds — Internal flows in impacting and coalescing mm-sized droplets, with different properties, in contact with a substrate is studied using two colour high-speed cameras (side and bottom views). This arrangement allows internal and surface phenomena to be distinguished, and hence the true extent and mechanism of mixing to be determined. Given enough lateral droplet separation, the impact droplet inertia generates a surfactant wave, which can be enhanced or suppressed through Marangoni flow by modifying the surface tension difference between the droplets. Conditions promoting good mixing are established, with practical implications for lateral separation and deposition order.

3:13PM A22.00002 Numerical investigation of collision of two liquid metal droplets under the influence of magnetic field. JIAICAI HUANG, JIE ZHANG, Xi’an Jiaotong University China, KIRTI SAHU, Indian Institute of Technology Hyderabad, India, MINGJIU NI, University of Chinese Academy of Sciences, Beijing, China — We investigate the collision dynamics between liquid GaInSn droplets under the influence of an applied magnetic field by conducting three-dimensional numerical simulations. The surface tension between liquid metal droplets is much larger than that of the normal liquid droplets. The collision dynamics is influenced by a large number of parameters, namely, the Weber number, Reynolds number, separation distance and the relative velocity of the droplets, along with the applied magnetic field. We have validated our solver by comparing with the earlier experimental results without the magnetohydrodynamics (MHD) effect. Different regimes of coalescence and separation dynamics are observed without the MHD effect and found to show excellent agreement with the earlier experiments. Then we study the effect of the external magnetic field and its direction on the droplet dynamics and regime map of the distinct coalescence behaviors. The underlying physics of the collision dynamics of liquid metal droplets has been analyzed using the resultant flow field.

3:26PM A22.00003 Coalescence dynamics of a droplet on a sessile droplet. MANISH KUMAR, RAJNEESH BHARDWAJ, Department of Mechanical Engineering, Indian Institute of Technology Bombay, Mumbai 400076, India, KIRTI CHANDRA SAHU, Department of Chemical Engineering, Indian Institute of Technology Hyderabad, Sangareddy 502 285, Telangana, India — The coalescence dynamics of an ethanol droplet freely falling on a sessile ethanol droplet resting on glass substrate is investigated experimentally using a high-speed imaging system. The sessile glass surface is found to be 24with a standard deviation of 1.3. The regime maps showing the partial and the complete coalescence behaviors in the plane of the normalized impact height and the volume of the sessile droplet with the diameter and the volume of the impacting droplet are presented. It is observed that the partial coalescence of satellite droplet occurs when the ratio of the volume of the sessile droplet to that of the impacting droplet is greater than two. The size of the satellite droplet is found to be about 0.1 times the size of that of the impacting droplet, which increases with the increase in the normalized impact height and normalized volume of the sessile droplet.
3:39PM A22.00004 Coalescence of Liquid Metal Droplets with application to metallic 3D printing, RYAN MCGUIN, PIROUZ KAVEHPOUR, ROB CANDLER, UCLA — In the field of additive manufacturing, printing functional metallic parts remains the ultimate challenge and goal of research and industry. Metals present many challenges due to high thermal conductivity, their tendency to oxidize and sensitivity to thermocapillary effects. Understanding and mitigating these variables is necessary for the process to become workable, scalable and economic. For droplet-based 3D printing, it is essential to study the liquid droplet coalescence on a planar surface presents a challenging crucible of physical forces including viscosity, capillarity, inertial and gravitational body force. This is further complicated in some of applications such as droplet coalescence in a “quasi-film” confined to the air-metal or liquid-metal (in the case of surrounding the droplet with an immiscible liquid) interface. This oxidation layer introduces inhomogeneity of material properties at the surface, as well as interfacial phenomena that defy traditional models of surface tension or interfacial energy driven interactions. We investigated the coalescence of room temperature liquid metal and its unique features. The coalescence process is studied for metallic droplets with and without oxidation. We observed that many features of this phenomenon differ from non-metallic drop coalescence.

3:52PM A22.00005 Droplet propulsion on a superhydrophilic wire induced by coalescence, ALLISON O’DONNELL, YOUMHU JIANG, KYOO-CHUL PARK, Northwestern University — Prior research has reported that droplets can jump from both superhydrophobic flat surfaces and hydrophobic cylindrical wires upon coalescence. As the surface area of droplets reduces after coalescence, released surface energy transitions to kinetic energy, causing the droplet to jump. Our findings indicate that droplet propulsion induced by the same surface-to-kinetic energy transition also occurs on superhydrophilic wires. In this experiment, droplets are sequentially deposited on an inclined superhydrophilic wire at a controlled rate. As the droplets wet the wire and flow downward, adjacent droplets may merge. In such cases, droplet speeds before and after coalescence are measured. This is repeated with droplets of differing viscosities and surface tensions and on wires of varying diameters. The results suggest that the ratio of increased kinetic energy to available surface energy is less than 4%. Additionally, it decreases as viscosity increases, surface tension decreases, and wire diameter increases. This trend can be attributed to the energy loss from viscous friction as droplets oscillate during coalescence. A scaling law is also provided to explain this trend. The phenomena reported in this study provide new insights into liquid transport on wires.

4:05PM A22.00006 Self-Similar Coalescence of Liquid Lenses, MICHIEL HACK, WALTER TESUY, KIRSTEN HARTH, University of Twente, QINGGUANG XIE, JENS HARTING, Eindhoven University of Technology, JACCO SNOEIJER, University of Twente — The coalescence of droplets is of key interest to many industrial applications, such as inkjet printing and spray formation. Here, we study the initial stages of coalescence of liquid lenses, consisting of droplets floating on a liquid pool. Using high-speed imaging, we find that the bridge grows with self-similar dynamics, with different scaling laws at low and high lens viscosities, indicating the existence of two coalescence regimes. We provide an analytical description based on the slender geometry of the system, using the two-dimensional thin sheet equations. Excellent agreement is found with the experiments, capturing both the exponents and the detailed spatial structure of the similarity solution in both regimes. Finally, we show that all data collapse on a single curve capturing the full range of the coalescence dynamics.

4:18PM A22.00007 Shear-induced non-coalescence for contactless droplet bearings, MICHELA GERI, BAVAND KESHAVARZ, GARETH MCKINLEY, Mechanical Engineering, MIT — Coalescence between a drop and a bath of the same liquid can be delayed or even completely suppressed if the lubricating air layer separating the approaching liquid surfaces is replenished. Thermal Marangoni stresses can promote such scenario if an initial temperature difference is imposed between drop and bath. Even when the droplet is left to thermally equilibrate coalescence can be delayed for many seconds, with the delay time being an increasing power law of the temperature difference. Under isothermal conditions coalescence can be suppressed if the droplet is externally forced to move over the liquid surface. This motion continuously replenishes the air cushion separating the droplet and bath while inducing fluid recirculation within both liquids. We use a custom setup that allows us to carefully control the speed at which the drop is kept in motion over the bath. By pinning the droplet to a force transducer we measure the friction force that is generated by the lubricating air flow for different velocities and different fluid viscosities. We discuss our results in view of a lubrication analysis for the air flow within the gap and investigate the possibility of using this technique to generate contactless droplet bearings.

Saturday, November 23, 2019 3:00PM - 4:31PM — Session A23 Bubbles: Surfactants and Foams

3:00PM A23.00001 Energy balance and the velocity gap in foam fracture, SASCHA HILGENFELDT, Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, PETER STEWART, School of Mathematics and Statistics, University of Glasgow — It has been shown experimentally and in simulations that a quasi-two-dimensional foam bubble layer, when driven under external stress, can display ruptures of successive films that constitute an analogue to brittle type-I fracture. Simplified discrete and continuum models from first principles of fluid dynamics capture the features of propagation, including the existence of a critical speed below which steady fracture cannot be sustained (velocity gap). In order to understand the magnitude and parameter dependence of the velocity gap, it is advantageous to strike an energy balance in the system and thus connect with continuum dynamical fracture mechanics. The crack dynamics is characterized by system size (because of changes in strain energy concentration) as well as by dissipation effects in the foam. Access to an explicit analytical formalism for the modeling of all physical effects complements the simulation results and reveals general principles governing the occurrence of fracture velocity gaps.

3:13PM A23.00002 Active Foam: Connecting Structure, Dynamics and Control, LAUREL KROOK, Department of Mechanical Engineering, Stanford University, MATTHEW BULL, Department of Applied Physics, Stanford University, MANU PRAKASH, Department of Bioengineering, Stanford University — By inflating and deflating voxels within a polydisperse 2-D air-liquid foam, we demonstrate an experimental system where we perturb soft materials in a radially-symmetric manner. These cyclic perturbations can be coordinated spatially and temporally to encode (“write”) mechanical properties into the material. Using both a short-range mechanism (cascades of neighbor-swapping events) and a long-range mechanism (low-frequency acoustic), we discuss how to achieve a robust and morphable active material. Topics of interest include scaling analyses, noise, and accounting for complexity that arises from polydispersity and initial conditions. The goal of this work is to understand fundamental principles of confluent tissues and develop synthetic analogs.

1This research was co-financed by Oc-Technologies B.V., University of Twente, and Eindhoven University of Technology.
3:26PM A23.00003 Microfluidic-based foams: a possible template for photonic structures\textsuperscript{1}, ILHAM MAIMOUNI, MARIA RUSSO, MARYAM MORVARIDI, JANINE COSSY, PATRICK TABELING, Ecole Supérieure de Physique et de Chimie Industrielles, PSL, France — Through the past decades, foams have taken more and more place into our modern world and have been used in a myriad of applications such as insulation building materials, food industry and photo-catalysis thanks to their interesting structural properties. Recently, 2D foams have been investigated to be self-assembled materials exhibiting interesting photonic properties. In the present study, we aim at exploring the 3D foams case. In this perspective, microfluidic technologies are used to develop 3D, solid, highly monodisperse polymeric foams by packing air bubbles in aqueous solution containing a polymer. The bubbles are produced in a PDMS (Polydimethylsiloxane) microfluidic chip and directly assembled in a microfluidic channel giving birth to highly tunable 3D foam. Indeed, by varying fluid pressures, the foam composition and the polymerization process, we manage to sharply control bubbles production and thereby govern the structural properties of the obtained material: porosity, pores size, connectivity and polydispersity. Electromagnetic simulations are then performed to study wave propagation in such foams, revealing very interesting transmission regimes and opening the way for a new technological application of fluid-based systems.

3:39PM A23.00004 Evaporation induced spontaneous cyclic dimpling in binary mixtures and its role in bubble stability. VINEETH CHANDRAN SUJA, JAVIER TAJUELO, GERALD FULLER, Stanford University — Liquid mixtures having components with heterogeneous volatilities, such as lubricants, are known to support stable foams in the absence of surfactants. Recent studies have shown this is a consequence of stabilizing Marangoni flows induced by the differential evaporation of liquid components from the surface of the bubble. Interestingly, unlike surfactant induced Marangoni flows, evaporation induced Marangoni flows in fact change the thickness of bubble walls resulting in a fascinating phenomenon known as ‘spontaneous cyclic dimpling’. This phenomenon has been studied in the context of emulsion stability resulting from surfactant diffusion, however very little is known about evaporation induced spontaneous cyclic dimpling. Here we study this phenomenon in detail by visualizing the spatio-temporal evolution of the wall thickness of single bubbles in binary mixtures using white light interferometry. Various binary mixtures of silicone oils are tested to understand the mechanics of spontaneous cyclic dimpling and its influence on bubble stability as a function of species mole fraction, volatilities and viscosities.

3:52PM A23.00005 Effects of soluble surfactant and viscoelasticity on pressure-driven turbulent bubbly channel flow\textsuperscript{1}, ZAHEER AHMED, Koc University, Turkey, DAULET IZBASSAROV, PEDRO COSTA, OUTI TAMMISOLA, KTH Mechanics, Sweden, METIN MURADOGLU, Koc University, Turkey — Particle-resolved direct numerical simulations are performed to investigate the combined effects of soluble surfactant and viscoelasticity on structure of pressure-driven turbulent bubbly channel flow ($Re_c = 180$). Incompressible flow equations are solved fully coupled with FENE-P viscoelastic model and soluble interfacial and bulk surfactant concentration equations. A non-linear equation of state relates surface tension to interfacial surfactant concentration. The method is first validated using benchmark turbulent single- and two-phase flows. Then massively parallel simulations are performed to examine effects of viscoelasticity and surfactant on turbulent bubbly flows. We found that clean bubbles move toward the walls due to inertial lift force, resulting in formation of wall-layers and a significant decrease in the flow rate. An addition of strong enough surfactant alters the direction of lateral migration of bubbles resulting in a nearly uniform bubble distribution across the channel. For the viscoelastic case, shear-thinning effects promote inertial lift, enhancing formation of bubbly wall-layers and consequently strong decrease in the flow rate. Formation of wall-layers is determined by the interplay of viscoelasticity and surfactant, when they act together.

4:05PM A23.00006 Direct Numerical Simulations of the Three Dimensional Dynamics of Surfactant Laden Bursting Bubbles\textsuperscript{1}, DAMIR JURIC, LIMSI, CNRS, France, RICARDO CONSTATE-AMORES, ASSEN BATCHVAROV, LYES KAHOUADJI, Imperial College London, SEUNGWON SHIN, Hongik University, South Korea, JALEL LAHOUADJI, CRISTIAN CONSTATE-AMORES, RICHARD CRASTER, OMAR MATAR, Imperial College London — Bursting bubbles play an important role in both industrial applications and nature with $\sim 10^{14}-10^{20}$ bubble bursts per second over the oceans, exchanging chemical components or heat between the ocean and the atmosphere. When a bubble is close to a free surface, it forms a hole which leaves an open unstable cavity that will collapse; the change of the interface curvature leads to the formation of a central jet, which breaks into droplets according to the Plateau-Rayleigh instability. The surfactant-free interfacial dynamics are well understood but the surfactant-laden ones are not. Neglecting gravity, the Laplace number is the only remaining control parameter measuring the relative importance of surface tension to viscous forces i.e. $La = \rho R \sigma / \mu^2$, where $\rho$, $\mu$, $\sigma$, and $R$ are the liquid density, viscosity, surface tension, and the initial radius of the droplet, respectively. 3D DNS simulations varying the Peclet number, $Pe = UR/D$, where $U$ and $D$ denote the velocity and diffusion coefficient, respectively, were performed to analyse the fate of the jet. Results regarding the interfacial surfactant concentration distribution, the surface tension gradients, and the importance of Marangoni stresses on the jet formation will be presented.

\textsuperscript{1}Funding from BP, EPSRC, PETRONAS, RAEng.

4:18PM A23.00007 The effect of surfactant on the tail dynamics of elongated bubbles\textsuperscript{1}, OMAR MATAR, ASSEN BATCHVAROV, Imperial College London, MIRCO MAGNINI, University of Nottingham, LYES KAHOUADJI, CRISTIAN CONSTATE-AMORES, RICHARD CRASTER, Imperial College London — Following the classical work by Bretherton and Taylor, the propagation of elongated gas bubbles in micro-channels has received a great deal of attention in the literature due to its relevance to a wide range of applications. Recent work by Magnini et al. Phys. Rev. Fluids, 023601 (2018) and Moran et al. (Bulletin of the American Physical Society, vol. 63, D09.00002) has also examined these flows (with concurrent liquid flow) with significant buoyancy and inertial effects in both vertical and horizontal configurations. The present work focuses on bubble tail undulations in the presence of surfactants whose effects merit attention. We carry out three-dimensional direct numerical simulations of the flow using a hybrid front-tracking/level-set method (Shin et al., J. Comput. Phys. 359, 409-435, 2018) over a wide range of surfactant properties including diffusivity, elasticity, and solubility. The effect of these properties on the speed of bubble propagation and interfacial shape is examined, paying particular attention to the bubble tail dynamics at high Reynolds number.

\textsuperscript{1}We acknowledge gratefully the contribution of Drs Damir Juric and Jalel Chergui (both from LIMSI, CNRS, France), and Dr Seungwon Shin (Hongik University, South Korea), in terms of code development, and funding from EPSRC (grant EP/K003976/1), and the Royal Academy of Engineering (Research Chair for OKM).
3:00PM A24.00001 Linear Stability of Taylor Bubbles in Downward Flowing Liquids\(^1\), HABIB ABUBAKAR, OMAR MATAR, Imperial College London — A Taylor bubble rising against a downward flowing liquid in vertical pipes is known to lose its symmetric shape when the velocity of the liquid exceeds a critical value. The influence of the liquid flow conditions, characterised by the dimensionless Eötvös number, \(E\_o\), and inverse viscosity number, \(N\_v\), on the onset of transition from symmetric to asymmetric bubble shape, is examined using linear stability analysis. To gain insight into the underlying mechanism, an ‘energy’ budget analysis is carried out to isolate the most dominant energy term that drives the instability. The analysis shows that the driving mechanism is dependent on whether or not the effect of surface tension can be neglected. For negligible surface tension effects, the instability originates from within the bubble and the dominant source of energy that drives the instability is related to perturbations in the bubble pressure. In the case of strong surface tension, the mechanism is related to disturbances connected to the interfacial stress condition.

3:13PM A24.00002 Numerical Modelling of Phase-change: Application to Evaporating Taylor Bubbles in Superheated Rectangular Microchannels\(^1\), YAN DELAURE, Dublin City University, THOMAS ABADIE, OMAR MATAR, Imperial College London — In micro-structured devices, the high surface to volume ratio leads to enhanced transport phenomena and the design of micro heat-exchangers requires some fundamental understanding on the dynamics and transfer phenomena taking place. The present study therefore aims at presenting a simple but accurate continuous model for modelling phase change in microfluidic devices within a finite volume Navier-Stokes flow solver. The proposed model is based on a Level Set method for capturing the interface on a fixed structured cartesian mesh and a continuous surface force method for the capillary force. The temperatures are solved in each phase in a sharp way in order to estimate the temperature gradients and the interfacial heat flux accurately. The accuracy of the phase change model is assessed with the analytical solution of the growth of a bubble in a superheated liquid. The evaporation rate of bubbles in superheated rectangular microchannels is investigated in the liquid film regime and the effects of geometry (aspect ratio) are studied. The effects of liquid superheat and operating conditions and thereby liquid film and thermal boundary layer thicknesses are discussed in terms of wall and interfacial heat fluxes.

3:26PM A24.00003 Quantitative Phase Field Simulations of Turbulent Two-Phase flows\(^1\), NATHAN LAFFERTY, Paul Scherrer Institute, ARNOLDO BADILLO, OMAR MATAR, Imperial College London — Turbulent two-phase flows are ubiquitous and fundamental in our society. We find them in ordinary tasks such as cooking (boiling), but also in more complex systems such as internal combustion engines, power stations, and atmospheric flows just to name a few. A better understanding of the interaction between turbulent structures and interfaces, will contribute to the derivation of more accurate models, which can then be used in the optimization of current technologies or aid in the development of new ones. To assess the capabilities of the Phase-Field model in predicting turbulent two-phase flows, we simulate the dynamics of a Taylor bubble rising in a cylindrical pipe. The simulations lead to the formation of a complex turbulent pattern in the wake of the Taylor bubble, which is strongly coupled to the dynamics of the bubble skirt. We observed important changes in the turbulent structures, as we vary the level of resolution of the surface tension force. We compare our prediction of bubble rise velocity, mean velocity profiles and turbulent fluctuations with direct experimental measurements. We discuss our findings, in terms of a recently developed analytical expression for the physical error in the calculation of the surface tension force.

\(^1\)We acknowledge funding from the Royal Academy of Engineering (Research Chair for OKM) and EPSRC (grant EP/K003976/1).

3:39PM A24.00004 Violent Expansion of a Rising Taylor Bubble\(^1\), GUANGZHAO ZHOU, ANDREA PROSPERETTI, University of Houston — Because of the gradually decreasing hydrostatic pressure, a Taylor bubble expands as it rises in a long vertical conduit such as are encountered in volcanoes and deep-water oil drilling. In some situations, the expansion becomes violent, with a rapid increase of the bubble volume and a possibly catastrophic ejection of liquid from the mouth of the conduit. The mechanism of this process is analyzed with a 1-D drift-flux model and a simpler dynamic model. The results of the two models agree with each other. A simple but useful criterion for the occurrence of the violent expansion is obtained from a quasi-equilibrium model. The important nondimensional parameters involved in the process are identified and, on their basis, the energy budget for the rising bubble is clarified. The effect of gas diffusing from the liquid into the rising bubble is also considered and deficiencies in the current state of knowledge about this aspect of the problem are identified.

3:52PM A24.00005 How fast do bubbles rise in strong turbulence with a high energy dissipation rate?\(^2\), RUI NI, ASHWANTH SALIBINDLA, ASHIK ULLAH MOHAMMAD MASUK, Johns Hopkins University — We carried out an experimental study on the rise velocity of finite-size bubbles from 1 mm to 10 mm in diameter in strong turbulence. The turbulence generated in our facility targets an energy dissipation rate close to the one typically experienced in oceanic environments, which is orders-of-magnitude larger than most existing laboratory facilities. To uncover the mechanisms of bubble-turbulence interaction and its effect on the bubble rising velocity, simultaneous measurements of both the dispersed and the carrier phases in 3D were obtained. The results suggest that the bubble rising velocity shows an interesting transition: small bubbles rise much slower and large bubbles rise faster than that in the quiescent medium. In addition, the transition is at the point when bubble deformation becomes important. A simple model is introduced to quantify this transition and use it to infer both the lift and drag coefficients.

4:05PM A24.00006 Path transition of a spiraling rising bubble: a wake-controlled process by imposing magnetic fields

JIE ZHANG, School of Aerospace, Xi’an Jiaotong University, LONG CHEN, MINGJIU NI, School of Engineering Science, University of Chinese Academy of Sciences — The path transition of a spiraling bubble under the influence of magnetic fields are investigated. It is found that the rising path of a spiral bubble can be controlled manually by imposing magnetic fields in different directions and magnitudes. To detect what happens to the bubble when magnetic fields are applied, two research strategies have been adopted. First we look into details at the evolution of the wake vortices after imposing magnetic fields, and we will show the path transitions and the closely related to the wake evolutions. Second, by calculating the time histories of the forces experienced by the bubble in presence of external magnetic fields, the results also reveal how the forces and the vortex patterns are coupled during path transition. Generally, the present study aims to provide the possibility of controlling the motion of bubbles, and potentially, this possibility conveys us that the key to control the bubble motion is to reconstruct the wake vortices by changing the flow field.

4:18PM A24.00007 Laboratory Experiments on Air Bubbles Rising through Carbopol Capped with Water

KAI ZHAO, EDMUND TEDFORD, Department of Civil Engineering, University of British Columbia, MARJAN ZARE, Department of Mathematics, University of British Columbia, IAN FRIGAARD, Departments of Mathematics and Mechanical Engineering, GREGORY LAWRENCE, Department of Civil Engineering, University of British Columbia — We have conducted a series of laboratory experiments bubbling air through a Carbopol solution capped with water. These experiments were conducted to better understand methane ebullition, and its effects on turbidity, in a pit lake. The first bubble is the largest and drags Carbopol into the water. Subsequent bubbles are smaller and follow the path of the first bubble, creating a tube within the Carbopol into which water flows. For a range of Carbopol concentrations we investigate the size and shape of the bubbles, their rise trajectory, the amount of Carbopol dragged into the water, and the evolution of the tubes. Higher concentrations of Carbopol can support deeper tubes without collapsing. These tubes resemble the pothole marks observed in the pit-lake bed.

Saturday, November 23, 2019 3:00PM - 4:31PM – Session A25: Bubbles I

3:00PM A25.00001 Shock wave interactions in single-bubble collapse near a corner

WILLIAM WHITE, SHAHABODDIN AALAHYARI BEIG, ERIC JOHNSEN, University of Michigan — Damage to neighboring surfaces due to repeated bubble collapse is one of the most important consequences of cavitation, which can be found in a multitude of hydraulic systems. A number of experimental studies have been conducted to predict the dynamics of re-entrant jets as well as bubble migration in a corner. However, the temperatures and pressures during the collapse have yet to be investigated. In this study, we quantify the effects of bubble-boundary interactions on the bubble dynamics and the temperatures/pressures produced by the collapse of a single bubble near two perpendicular rigid surfaces. For this purpose, we use an in-house, high-order accurate shock- and interface-capturing method to solve the 3D compressible Navier-Stokes equations for gas/liquid flows. The non-spherical bubble dynamics are investigated, and the subsequent pressure and temperature fields are characterized based on the relevant parameters entering the problem: geometry, stand-off distances from each surface, driving pressure. We demonstrate that bubble-boundary interactions amplify/reduce pressures and temperatures produced during the collapse and increase the collapse time and the non-linearity of the bubble displacement, depending on geometric parameters.

3:13PM A25.00002 The role of compressibility and vorticity in the collapse of a bubble near a rigid boundary

MINKI KIM, SHAHABODIN AALAHYARI BEIG, ERIC JOHNSEN, University of Michigan, Ann Arbor — Cavitation-bubble collapse is known to cause structural damage in a variety of industrial applications such as naval hydrodynamics and turbomachinery. The concentration of energy and shock emission during the non-spherical collapse is expected to depend on the liquid compressibility, and possibly the vorticity produced during the process. Thus, a better understanding of role of compressibility and vorticity is essential to predicting cavitation erosion. In this study, we compare direct simulations to potential flow calculations to extract the effects of compressibility and vorticity on the collapse of a gas bubble near a rigid boundary. The 3D compressible Navier-Stokes are solved in the gas and liquid using a high-order shock- and interface-capturing scheme; potential calculations are conducted using a boundary integral method. We observe a delay between the two approaches, attributed to the differences in the pressure fields at early times due to compressibility effects. Nevertheless, bubble morphologies are similar for most of the collapse, with discrepancies visible only in the last stage of collapse. The vorticity evolving during the collapse may play a role on the bubble dynamics at this stage.

3:26PM A25.00003 Collapse of individual bubbles near rigid boundaries

SHAHABODIN AALAHYARI BEIG, ERIC JOHNSEN, Mechanical Engineering Department, University of Michigan — Cavitation happens in a variety of applications ranging from naval hydrodynamics to biomedical ultrasound. The inertial collapse of cavitation bubbles concentrates energy into a small volume, and is capable of producing high pressures and temperatures and emitting radially propagating shock waves. One important consequence of such phenomenon is structural damage to neighboring objects following repeated collapse of cavitation bubbles. In order to provide a better understanding of this problem, we perform high-resolution numerical simulations of the inertial collapse of individual bubbles near rigid surfaces by solving the three-dimensional compressible Navier-Stokes equations for gas/liquid systems. By considering the collapse of a single bubble as well as a bubble pair near a rigid surface, we explain that the bubble-boundary and/or bubble-bubble interactions can affect the energy concentration, give rise to the kinetic energy of non-converging motions, and break the symmetry of the collapse that modify the pressures and temperatures thereby produced. The results are used to investigate the non-spherical bubble dynamics and characterize the pressure and temperature fields based on the relevant parameters entering the problem: initial stand-off distance, distance and angle between the two bubbles, and driving pressure This work was supported by ONR grant N00014-12-1-0751 under Dr. Ki-Han Kim.

3:39PM A25.00004 ABSTRACT WITHDRAWN –
3:52PM A25.00005 The diameters and velocities of the jet droplets produced after bubble bursting, FRANCISCO J. BLANCO-RODRIGUEZ, JOSE M. GORDILLO, Universidad de Sevilla — Here we provide a theoretical framework revealing that the radius \( R_0 \) of the top droplet ejected from a bursting bubble of radius \( R_0 \) can be expressed as

\[
R_0 = \frac{0.22 R_0}{1 - \left( \frac{2\mu}{\rho R_0^2} \right)^{1/2}}
\]

for \( Oh \ll 0.3 \) and \( Bo \ll 1 \) with \( Oh = \mu/\sqrt{\rho\sigma} \ll 1 \) the Ohnesorge number, \( Bo = \rho g R_0^2/\sigma \) the Bond number and \( \rho, \mu, \) and \( \sigma \) the liquid density, viscosity, and surface tension coefficient respectively. This prediction, which agrees very well with both experimental data and numerical simulations for all the values of \( Oh \) and \( Bo \) investigated, can be particularized to express the diameters of the jet droplets produced from the bursting of sea bubbles with radii \( R_0 \leq 1 \) mm, with implications in marine aerosol production. The velocities of the first drops ejected are also expressed as a function of \( Oh \) and \( Bo \), being this initial drop velocity largely reduced by air drag at tiny distances \( \sim R_0 \) above the interface. We find that the ratio between the radius of curvature at the tip of the jet and the jet radius controls the growth of capillary instabilities, a fact explaining why no droplets are ejected from the tip of the fast Worthington jet for values of \( Oh \) slightly larger than \( Oh^{0.3} \).

Saturday, November 23, 2019 3:00PM - 4:31PM –
Session A26 Experimental Measurements: General - 608 -

3:00PM A26.00001 Micro-PIV Evaluation of Lateral Flow Assays, EMILIE NEWSHAM, STEVE WERELEY, JACQUELINE LINNES, Purdue University — Lateral flow assays (LFAs) are an increasingly common technology (e.g. pregnancy tests) but are limited in scope and sensitivity due to minimal understanding of their underlying fluidic properties. LFAs comprise porous paper membranes that transport liquid samples along a test strip through capillary action to dried reagents, where binding reactions produce a readable signal. Mathematical models informed by analytical evaluations have been created to optimize LFA development, but none use empirical microfluidic data to derive model parameters. Here, micro-PIV is used to evaluate liquid flow in LFAs. Videos of liquids carrying nanoparticles flowing through LFA membranes under different conditions are analyzed using micro-PIV. The porous membrane has different permeability to the liquid and nanoparticles which means the observed particle motion is not the same as the fluid motion. A scale factor between the visible macroscopic fluid front and microscopic particle velocity is derived. This novel microscopic evaluation method will inform intelligent models for more efficient development of LFAs.

3:13PM A26.00002 V3V Measurements on a Propeller in a Cavitation Water Channel, DAN TROOLIN, WING LAI, TSI Incorporated — Cavitation around ship propellers occurs due to low pressure regions where cavitation bubbles form and collapse potentially causing severe damage to propeller blade surfaces through unequal loading, vibration, and pitting. In order to avoid cavitation damage care must be taken in the design, selection and operation of the propeller blades. A study was conducted in the West Japan Fluid Engineering Laboratory Co., Ltd. closed return cavitation water channel with a test section of 500 500 2000 mm of the flow downstream of a five-bladed, powered aquatic propeller at a freestream velocity of 4.0 m/s. A V3VFlex volumetric measurement system with four 4 megapixel cameras was used in order to provide high-resolution instantaneous and phase-averaged volumetric measurements. The measurements reveal the presence of vortex structures, locations and interactions. Results of the propeller wake will be presented and examined.

3:26PM A26.00003 Gridded Analysis of Volumetric Particle Velocity Data, MATT STEGMEIR, TSI Incorporated — 2-Frame and time-resolved Volumetric Particle Tracking has become an increasingly valuable tool for 3-D flow characterization. Unstructured, randomly-distributed data are typically produced by tracking individual particle locations either between 2 sequential image frames or by constructing longer Lagrangian particle position tracks to from highly time-resolved data. High-resolution datasets are typically interpolated onto an ordered grid in order to provide greater convenience in data presentation and to facilitate calculation of derived quantities. Interpolation schemes are compared for accuracy and resolution, and robustness to spurious data points. Improvements are proposed to provide for increased resilience against noise and spurious data points in experimental data sets. Results are compared to standard Gaussian-weighted interpolation. Single- realization and statistical results are presented from analysis of synthetic and experimental datasets.
3:39PM A26.00004 Droplet sizing of opaque liquid with integrated transmitting and receiving optical arrangement. WING T. LAI, DANI TROOLIN, TSI Incorporated — A number of industrial applications require the precise sizing of droplets. Some examples are spray drying in drug formation and ink jet printing for TV panels. The technique of ink jet printing for making TV panels requires the droplets emitting from the printer nozzles to be monodisperse and uniform for a long period of time. A typical printer head consists of multiple nozzles, from 256 to 1046. Every nozzle is designed to be producing the same droplet size of liquid over the period of time when the panel is being made. Hence it is important to be able to monitor all the nozzles regularly to ensure that the uniform droplets are produced. If there is any size deviation of the droplets from the nozzles, the quality of the panel can be substantially degraded, making it non-useable. An integrated transmitting and receiving optical probe was designed specifically for the measurement of the droplets from all the nozzles in a sequential fashion such that every nozzle in the printer head can be characterized. The droplet result provides the feedback of any faulty nozzle behavior (one not giving the correct droplet size) and adjustment of the flow system can be made to get the nozzle working normal again.

3:52PM A26.00005 Development of a Flexible Four-Camera Volumetric PIV System for Tow Tank Applications. RUBEN HORTENSIIUS, STAMATIOS POTHOS, MARK CECCONI, TSI Incorporated — Traditionally PIV experimentation for hydrodynamic, marine, and biological applications, have been carried out in water tunnel facilities, where the instrumentation is safely located outside of the facility. Due to practical constraints, this has often resulted in limited ability to conduct experiments at large scale or at high magnifications. To overcome this, submersible PIV systems have been developed, allowing for PIV experimentation in facilities such as towing tanks. These tow tank PIV systems, whether 2D/planar-PIV or 3D/stereo-PIV, are still regarded as very unique and highly specialized, in no small part due to the exceptionally distinctive facilities which house them. TSI has provided numerous PIV systems for underwater applications in the past, and in 2017 produced a specialized system capable of being used for 2D/planar measurements, 3D/stereoscopic measurements, and 3D3C volumetric measurements. Details of the capabilities of the new system are described, as well as insights gleaned from the design, manufacture, and installation of this one-of-a-kind system. Preliminary volumetric PIV results obtained with the system are shared and discussed.

4:05PM A26.00006 Volumetric 3D-3C (V3V) Particle Tracking Velocimetry measurement of turbulent twin jet. NIMESH VIRANI, VESELINA ROUSSINOVA, Department of Mechanical, Automotive and Materials Engineering, University of Windsor, RAM BALACHANDAR, Department of Civil and Environmental Engineering, University of Windsor — Recently developed (by TSI, Inc., Shoreview, MN, USA) V3V: Volumetric three-direction, three-component (3D-3C) particle tracking velocimetry technique, is applied for understanding of inherently complex interaction between turbulent twin jets. Two jets are separated by a distance of approximately 2D, where D is the diameter of the jet and Reynolds number based on exit diameter of the pipe, for both jetting velocimetry technique, is applied for understanding of inherently complex interaction between turbulent twin jets. Two jets are separated by a distance of approximately 2D, where D is the diameter of the jet and Reynolds number based on exit diameter of the pipe, for both jets is around 12000. Jets are released into a channel comprising of quiescent water and channel dimensions are such that, jets can remain free from any kind of boundary effects. The measurement volume of approximately 15010050 mm^3 in X, Y and Z directions, which is equivalent to 63D42D21D in terms of pipe diameter, was investigated for mean and turbulence characteristics of problem under consideration. Particle tracking velocimetry (PTV) is applied to trace randomly spaced seeding particles between concurrently captured two frames of the same instant of flow field. PTV eliminates inherent bias present in the traditional FFT correlation based analysis of particle image velocimetry (PIV). Access to all three components of velocity enabled us to get insight of shear layer merging phenomena between two jets, which resulted into some interesting instantaneous flow structures. Time-averaged and turbulent characteristics of jets’ interaction are analyzed using various statistical analysis tools and they reiterate the necessity of 3D examination.

4:18PM A26.00007 Experimental Characterization of Flow Induced by a Nanosecond Surface Discharge. LALIT RAJENDRAN, BHAVINI SINGH, RAVICHERA JAGANNATH, GEORGE SCHMIDT, PAVLOS VLACHOS, SALLY BANE, Purdue University — Nanosecond surface Dielectric Barrier Discharges (ns-DBD) have generated growing interest as a means of high speed flow control. These discharges are characterized by electrical breakdown caused by high voltage, nanosecond pulses resulting in ultra-fast heating of the surrounding air. The rapid heat release leads to generation of a shock wave and complex flow characterized by coherent vorticity and a hot gas kernel near the electrode surface. Past applications of these discharges have yielded mixed results in flow control and the reasons for success/failure of these actuators are not well understood. This is because a fundamental understanding of the induced flow field and its relation to electrode geometry and energy deposited is not available. To address this limitation, we have performed high speed Particle Image Velocimetry (PIV) and Background Oriented Schlieren (BOS) measurements on the flow induced by a single nanosecond filamentary surface discharge under quiescent conditions. We measure the vorticity and density of the hot gas kernel and create a mechanistic model of the actuator induced flow. Such a model of the actuator performance can inform the choice and deployment of these devices for flow control applications.

Saturday, November 23, 2019 3:00PM - 4:31PM – Session A27 Biological Fluid Dynamics: Flight 609 - Geoffrey Spedding, USC

3:00PM A27.00001 Unsteady aerodynamic characteristics of large scale bird flapping flight. ZIFENG WENG, School of Mechanical Engineering, Shanghai Jiao Tong University, Shanghai, 200240, China, SUYANG QIN, YANG XIANG, HONG LIU, J. C. Wu Center for Aerodynamics, School of Aeronautics and Astronautics, Shanghai Jiao Tong University, Shanghai, 200240, China — Various unsteady aerodynamic mechanisms have been found in flapping flight especially at low Reynolds number (1E2-1E4). However, large scale bird flying at high Re (1E5) is mostly assumed to be quasi-steady. A two-jointed-wing robotic goose was built to carry out wind tunnel experiment. Force and PIV measurements were performed to study the unsteady force and flow field. Lift is found to change with average effective angle of attack and the average lift is close to that in cruising flight. Lift enhancement occurs in mid-downstroke, which is not induced by leading edge vortex but the result of enhancement of circulation. Thrust occurs in both upstroke and downstroke periods, and maximizes at mid-upstroke and mid-downstroke. Since flapping amplitude varies along wing span, thrust production is the overall result at different spanwise position. According to the flow field measurement, jet flow is found in the wake of handwing, but not in that of armingwing. The phase difference between handwing and armingwing results in larger flapping amplitude, i.e. higher St and thus enhances thrust production. In general, high Re flapping flight play its role mostly in propulsion, instead of producing high lift as that in low Re flight. And lift production might rely more on aerofoil and flow speed.
3:13PM A27.00002 Simulation of flapping bird flight, part 1: closed-loop control, forces, and wake topology1, VICTOR COLOGNESI, GIANMARCO DUCCI, RENAUD RONSSSE, PHILIPPE CHATELAIN, UCLouvain, REVEALFLIGHT TEAM — This work aims at reproducing bird flight in silico in order to shed light on its performance-enabling mechanisms. To that end, we establish an anatomical model of a bird with a pure flapping gait, the bald ibis. It combines a multi-body model of the skeleton, with the corresponding joints and degrees of freedom, and a plumage model. The latter allows extracting the wing geometry and aerodynamic properties for any configuration of the skeleton. These properties are translated into a deforming immersed lifting line, which handles the sources of vorticity within a vortex particle-mesh method. The resulting multiphysics framework captures, at a high fidelity, the full flight dynamics, the required efforts and the resulting wake. A sensitivity analysis is carried out and leveraged for the design of a flight controller. Specifically, we quantify the influence of shoulder kinematic features on the aerodynamic forces and moments. The controller then uses these features as command parameters. This bird model can reach a trimmed state over various flight regimes and can handle transients between them. Finally, the accurate capture of the wake vortical structures allows their unambiguous identification and association with the time-varying aerodynamic forces produced by the bird.

1This project was supported by the ARC program of the Federation Wallonie-Bruxelles (grant number 17/22-080, REVEALFLIGHT)

3:26PM A27.00003 Simulation of flapping bird flight, part 2: Gait parametrization, limit cycle, and dynamic stability1, GIANMARCO DUCCI, VICTOR COLOGNESI, PHILIPPE CHATELAIN, RENAUD RONSSSE, Universite catholique de Louvain, REVEALFLIGHT TEAM — We introduce a method to identify gait trajectories in trimmed flapping flight. Such trajectories correspond to limit cycles in the state space, characterized by the same period as the wingbeat. Our method relies on a multiple-shooting algorithm that can simultaneously identify unknown limit cycles, and analyze their stability. Based on Floquet theory, this analysis computes the Jacobian of the identified limit cycle and assesses its stability from its eigenvalues.

In a first contribution, we adapt this framework to the flapping flight equations of motion, known to be not only non-linear and time-dependent, but also driven by state-dependent forcing aerodynamic loads. An aerodynamic model was developed following the quasi-steady lifting line approach reported in part 1, taking the wing morphology and prescribed kinematics as input, and returning the state-dependent aerodynamic loads as output.

Our results identify one instable mode, suggesting that birds continuously rely on sensory feedback to achieve steady-state flapping flight. This framework is then leveraged in the analysis of several gait configurations. In particular, we use it to perform a sensitivity analysis of the flapping gaits required to achieve several flight regimes (level, climbing and descending flight).

3:39PM A27.00004 ABSTRACT WITHDRAWN —

3:52PM A27.00005 Holey wings can improve aerodynamics at bioscales, YOHANNA HANNA, GEOFFREY SPEDDING, University of Southern California — The performance of wings at moderate Reynolds numbers (10^3 \leq Re \leq 10^5) is strongly influenced by laminar boundary layer separation, and by the possible reattachment (in the mean sense) of the detached shear layer. Details of these events on both pressure and suction surfaces can lead to unexpected phenomena such as a negative lift slope around zero angle of attack, and abrupt changes in flow state close to the formation of a closed laminar separation bubble. Once understood, one may seek to exploit these sensitivities to find new forms of flow control, either passive or active. Here, we show that small, distributed porosity (porosity ratio, \phi = 0.005) on a wing at moderate Re can almost completely remove the nonlinearities in the C_l(\alpha) curve, to yield a more robust and predictable lifting device. The flow-through mechanisms of a permeable wing are investigated and provide an alternative explanation for the sometimes-reported benefits in bio-flyers, that would then also apply to engineered equivalents of the same scale.

4:05PM A27.00006 Arrow flight and optimal feathers in archery, TOM MADDALENA, CAROLINE COHEN, CHRISTOPHE CLANET, LaHyX, Ecole polytechnique — In archery, athletes shoot arrows with their bow from 70 m on an outdoor field. The target is made of 10 concentric rings, from 12 cm to 1.20 m. Therefore, the angular tolerance of the smallest ring is 0.12/70 = 2 mrad. What is more, the environmental conditions such as wind or rain can have a huge impact on the arrows final position. Yet, a few centimeters on the target often distinguishes the winner from the others. All parameters of the bow and arrows must then be carefully selected in order to maximize the accuracy. In this work, we focus on the arrows flight, and more particularly on the choice of the optimal feathers. Archers can indeed choose among many size and shapes of feathers, and the effect of those feathers on the accuracy is still poorly understood. To tackle this question, we combine different experiments. We first shoot arrows with feathers of different size and shape with a throwing machine. Those experiments are eventually achieved with a lateral wind. We also characterize in a wind tunnel the influence of the feathers on the aerodynamic forces on the arrow. Those experiments combined with a theoretical model of the flight, allow to predict the trajectory of an arrow, and the influence of different perturbation on its final position.

4:18PM A27.00007 Falling of a plate with eccentric center of mass, SEAN COUGHENOUR, HUI WAN, University of Colorado, Colorado Springs — The problem of a freely falling object is of interest in both fluid mechanics and nonlinear dynamics. Four types of motions have been observed, i.e., steady falling, flutter, tumble, and chaotic motion, depending on the body moment of inertia and the Reynolds number. For example, at high Reynolds number, flutter and tumble motion are obtained for bodies with small and large moment of inertia, respectively. Most of previous studies focused on the symmetric body with mass center collocated with the geometric center. In this study, we will numerically study the falling of a plate with eccentric center of mass. We will also adjust the center of the mass and thus change the moment of inertia and the angular velocity of body rotation, therefore enabling a new methodology to actively control the plate falling trajectories.
3:00PM A28.00001 Interaction Between Fibers and Viscous Flow Evaluated by Simplified Bead-Chain Model and Generalized SPH. YOSHIKAKI ABE, TOMONAGA OKABE, Tohoku University — This study investigates the motion of short fibers in melted resin for a three-dimensional (3D) printing process. We developed a numerical model for fiber and viscous-flow interaction problems based on the generalized smoothed particle hydrodynamics (generalized SPH) and the simplified bead-chain model (SBCM) for short fibers. The generalized SPH allocates particles inhomogeneously in a physical space and arranges them via mapping in a generalized coordinate system where the particles are aligned at a uniform spacing, which allows efficient simulation compared with conventional Cartesian SPH approaches. The SBCM models each fiber as a chain of spheres given by a single equation of translational motion. The effects of bending and hydrodynamic torques, which significantly simplify the governing equations and results in a more cost-effective simulation than conventional models such as the BCM or classical microstructure-based fiber suspension model. This study proposes the SBCM-SPH model for predicting a fiber-flow interaction and investigates the motion of short fibers in the fused decomposition modeling process of 3D printer.

3:13PM A28.00002 The Quest For Enhanced Pulsed Slurry Atomization Via Modulation. WAYNE STRASSER, Liberty University — Our non-Newtonian airblast atomization flowfield violently pulses (axially and radially) by self-generating and self-sustaining interfacial instability mechanisms. Recent work demonstrated that exothermic chemical reactions enhance this moderate Mach number atomization. Explored herein is the potential to further enhance reaction-assisted disintegration by superimposing forced mass flow variations onto otherwise constant gas feed streams. Two nozzle geometries (high and low prefilming distance) and multiple superimposed feed frequencies are considered for each gas stream. Results indicate that superimposed frequencies have potential to enhance chaotic atomization in a statistically significant manner. Ironically, the most efficient atomization did not coincide with the highest levels of gas resonance. A detailed study of reactor start-up flow reveals new mechanisms which explain performance differences. The prefilming design facilitates an isolated mixing region where secondary ignition occurs nearly immediately after startup and augments reaction product conversion.

3:26PM A28.00003 A novel selective lithium separation using amorphous pMOF/alginate interfaces. SUNG HO PARK, SANG JOON LEE, Pohang University of Science and Technology — Anomalous opposite ion behaviors of Li$^+$ and Mg$^{2+}$ ions are experimentally observed from amorphous interfaces of phosphonate metal–organic framework (pMOF)/alginate composites. The amorphous structures of pMOF/alginate composites are significantly varied according to reaction temperature and intertwinement degree of alginate networks. As a proof-of-concept application, Li$^+$ and Mg$^{2+}$ ions are separated using pMOF/alginate composite depending on the degree of pMOF growth. Initially, lots of Li$^+$ ions are effectively attracted compared to Mg$^{2+}$ ions due to the strong repulsion force of Al$^{3+}$ ions in amorphous alginate interfaces on multi-valent metal ions. However, amorphous pMOF/alginate interfaces induce effective rejection of Li$^+$ ions with low hydration energy through dehydration due to the significant interaction with water molecules, while Mg$^{2+}$ ions with high hydration energy are significantly attracted by negatively charged phosphonate groups. The present results of amorphous MOF/alginate interfaces would provide a variety of benefiting separation opportunities with unique property in seawater desalination and rare metal recovery.

3:39PM A28.00004 The impact of monovalent and divalent ions on the viscosity of a solution with silica nanoparticles. SAHEED OLAWALE OLAYIWOLO, MORTEZA DEJAM, Department of Petroleum Engineering, University of Wyoming, 1000 E. University Avenue, Laramie, WY 82071-2000, USA — Nanoparticles (NPs) are injected into the reservoirs for enhanced oil recovery. Several mechanisms like wettability alteration, reduction in the interfacial tension, and change in the rheological properties of the fluid are involved in this process. The rheological properties of the fluid depend on the interaction between the ionic components of the brine and the injected silica NPs. As a result, the flow is affected by the interaction of NPs and salt ions. The viscosity of fluid reduces with an increase in the temperature but the impact of the ionic components of brine on the viscosity of nanofluid is rarely investigated. Therefore, this study focuses on the effect of ionic components of brine (Na$^+$, K$^+$, Ca$^{2+}$, Mg$^{2+}$, Cl$^-$, and SO$_4^{2-}$) at different concentrations of silica NPs (0.01-1 wt%) on the viscosity of fluid. It was observed from the experimental data that the viscosity of fluid is increased by the divalent anions while it is reduced by the divalent cations. The interaction between the ions of NPs and the salt ions, which causes the variation in the viscosity of fluid, is further investigated by measuring the zeta potential and the particle size distributions.

3:52PM A28.00005 Unsteady fragmentation upon drop impact: Sheet dynamics. Y. WANG, L. BOUROUIBA, MIT — Prior work, Wang & Bourouiba 2018b, showed that upon drop impact on a finite surface, continuous secondary droplet shedding occurs, and that both size and speed distributions of the droplets ejected are governed by the unsteadiness of the sheet expansion. In turn, this continuous shedding influences the sheet expansion. Incorporating continuous droplet shedding, we show how the sheet is governed by a non-Galilean expansion law from which we predict the time evolution of all key physical quantities from the sheet radius to the fluid shed by the rim, all in agreement with experimental measurements. We also discuss a peculiar property of the governing equation which imposes a time-to-maximum-radius independent of the impact energy. This property results in a temporal evolution of the partition of mass, momentum, and energy in the sub-parts of the fragmenting system that is independent of the impact conditions. We discuss the robustness of the results to changes of fluid properties.

4:05PM A28.00006 Unsteady fragmentation upon drop impact: prediction of droplet size and speed distributions. L. BOUROUIBA, Y. WANG, MIT — Upon impact on a finite surface, a drop first expands into a sheet in the air, surrounded by a rim that destabilizes into ligaments that, in turn, shed secondary droplets. Wang & Bourouiba 2018b and Wang et al. 2018 showed that both size and speed distributions of the secondary droplets ejected during fragmentation are shaped by the unsteadiness of the sheet and rim. In this combined experimental and theoretical study, we derive and validate the analytic expression governing both size and speed distributions of secondary droplets ejected during such unsteady fragmentation, including time-evolution of the mean quantities associated with the distributions. We discuss the implications for various applications including contamination dispersal.

the number of patients who undergo orthodontic treatment of sleep apnea is increasing. Existing diagnostic methods, the polysomnography
YOUNG WOO KIM, JOON SANG LEE, HYUNG JU CHO, YOON JEONG CHOI, HWI DONG JUNG, Yonsei university, Seoul, Korea — Recently,
air can accumulate in the respiratory organs in the human body and cause various types of diseases. Various types of masks for filtering fine dust are
commercially available. Given the trade-off between the filtering performance and wearing comfort, the physical understanding of respiratory
mechanics through a mask is important in assessing the performance of the masks in mask design. We suggest an experimental setup to
evaluate the filtering performance and wearing comfort of dust masks. By constructing a respiration simulator, we measure dust particles that are
filtered by a mask and quantify the respiratory resistance in terms of the power required for respiration. We analyze the effects of additional
elements such as fans and valves attached to the mask to assist respiration.

3:39PM A29.00004 Computational analysis of airflow dynamics for predicting collapsible sites in the upper airways: Advanced machine learning
SUSIE RYU, SEUNG HO YEOM, YOUNG WOO KIM, JOON SANG LEE, HYUNG JU CHOI, YOON JEONG CHOI, HWI DONG JUNG, Yonsei university, Seoul, Korea — Recently, the number of patients who undergo orthodontic treatment of sleep apnea is increasing. Existing diagnostic methods, the polysomnography (PSG), however, have not been able to provide quantitative criteria and the non-scientific judgment method. Moreover, it is uncomfortable method to patent. In order to solve these problems, people try to use computational fluid dynamics (CFD) using upper airway geometry from the computed tomography (CT) data. The patients who have sleep apnea have considerable pressure drop occurred due to a narrow airway. This drop can be measured by using a pressure sensor placed on the airway. CFD modeling is used to predict the airflow through the airway for increasing the quantity of airway model data and simulate it to get aerodynamic features. Because of the requiring of heavy computational time cost, this study uses a machine learning algorithm. We use multivariate gaussian process machine learning for predicting aerodynamic features of unknown patients. This method can eliminate the high time consuming of CFD computation time. Also, we use Support vector machine learning algorithm to classify between normal and moderate OSAS patient. This algorithm classification showed about 80% classification accuracy that can be useful decision to clinician.

3:52PM A29.00005 Elasto-capillary network dynamics of inhalation
FELIX KRATZ, JEAN-FRANCOIS LOUF, Department of Chemical and Biological Engineering, Princeton University, ANVITHA SUDHAKAR, None, NATHANIEL JI, SUJIT DATT, Department of Chemical and Biological Engineering, Princeton University — The seemingly simple process of inhalation relies on the complex interplay between muscular contraction in the thorax, elasto-capillary interactions in the individual airway branches, connectivity between different branches, and overall air flow into the lungs. Sophisticated pulmonary fluid dynamics models have been developed to elaborate the competition between capillarity, which tends to keep flexible branches closed, and elasticity, which favors opening, for single airway branches. However, a quantitative model combining the physiological opening process of flexible airway branches with the biomechanics and interconnected geometry of the lungs is still missing. To address this issue, we develop a statistical model of the lungs as a symmetrically-branched network of liquid-filled cavities, interfaced to a viscoelastic network that represents the airway. The opening and closing of the airway is determined by input biomechanical parameters, enabling us to test the influence of changes in the mechanical properties of lung tissues and secretions on inhalation dynamics. By summing the dynamics of all the individual branches, we quantify the evolution of overall lung pressure and volume during inhalation, and find good agreement with typical breathing curves obtained in the literature.
3:00PM A30.00001 3D Confinement Effects on Helicobacter pylori Swimming, SURAJ KUMAR KAMARAPU, HENRY FU, University of Utah — H. pylori bacterium has evolved to swim through highly acidic gastric mucus layer by diffusing ammonia from its body, neutralizing the surrounding medium and forming a pocket of Newtonian fluid around itself. The shape of this pocket, which depends on the Peclet number, determines the overall swimming behavior of the bacterium. We previously used a 2D Taylor sheet model to study the swimming bacterium near a Brinkman medium that represented the mucus gel and found that the swimming speed monotonically increases as the distance between the swimmer and the gel decreases. However, swimming in such situations can also be highly dependent on boundary geometry, diffusion, swimming flows around the swimmer and requires a complete 3D model factoring in the above possible influences. Here we model the mucus gel with a random spatial distribution of regularized stokelets placed outside the Newtonian fluid pocket, and quantify its influence on the swimming speeds for a constant stroke. Advection-diffusion of ammonia is treated numerically allowing us to access large Peclet numbers. We find that for small Peclet numbers, the bacterium swims faster than predicted by a 2D model, but beyond a certain Peclet number, the bacteria can swim with reduced speed as it faces 3D confinement upstream.

3:13PM A30.00002 Motility of flagellated bacteria in colloidal media1, SHASHANK KAMDAR2, LORRAINE F. FRANCIS, XIANG CHENG, Department of Chemical and Materials Science, University of Minnesota Twin Cities — Recent years have seen increasing interests in understanding the mechanism and motility of microswimmers in non-Newtonian fluids due to their relevance in biological and biomedical applications. Nevertheless, despite extensive study on the locomotion of microswimmers in polymeric fluids, their motion in a colloidal suspension remains largely unexplored. Here, we study the motility of E. coli, a flagellated bacterium in colloidal medium. We systematically vary the size of colloidal particles from 50 nm to 1 μm and the volume fraction up to 20%. The motion of fluorescent-labeled bacteria is imaged using confocal microscopy and speeds of bacteria are extracted using a robust in-house tracking algorithm. Our results show that bacterial motility decreases with increasing volume fractions but remains constant beyond a critical volume fraction. In addition, we find that the motility depends on the size of passive colloid. Finally, we construct a simple model that qualitatively explains our experimental observation. This work enriches the current understanding of microswimmers’ locomotion in complex fluids.

3:26PM A30.00003 How Azimuthal Swirl Impacts Swimming Kinematics in a Viscoelastic Fluid1, JEREMY P. BINAGIA, Stanford University, ARDELLA PHOA, Santa Clara University, ERIC S. G. SHAQFEH, Stanford University — Microorganisms are often found moving through viscoelastic environments such as mucus layers or biofilms. In 2014, Zhu & Lauga simulated the steady motion of a spherical “squirmmer” in a viscoelastic fluid to understand how fluid elasticity impacts the organism’s speed. The squirmmer considers a spherical swimmer that includes a specified slip velocity at its surface. This model has been used extensively to study the motion of ciliates like Paramecium, colonies of the green algae Volvox, or as a simplified model for general swimmers like E. coli. In all cases, they found that a squirmmer swims slower than it does in a Newtonian fluid. In that study and many others that use the squirmmer model, only the first two axisymmetric swimming modes are considered. Only very recently have authors considered the addition of other modes, such as those that involve azimuthal surface velocities. Recently, we have conducted simulations showing that particular combinations of the axisymmetric swirling modes can actually lead to a speed increase in an elastic fluid. In this talk, we will describe how the inclusion of this azimuthal swirl affects swimming kinematics in elastic fluids, with a focus on how polymer deformation leads to changes in speed.

3:40PM A29.00007 Analysis of Inlet Velocity Profile Effects on Airflow Simulations in Patient-Specific Healthy Trachea, BIPIN TIWARI, Department of Aerospace Engineering, Auburn University, TARUN KORE, Department of Chemical Engineering, Auburn University, ZHENGLUN ALAN WEI, Wallace H. Coulter School of Biomedical Engineering, Georgia Institute of Technology, SANDEEP BODDULURI, SURYA P. BHATT, Department of Medicine, University of Alabama at Birmingham, VRISHANK RAGHAV, Department of Aerospace Engineering, Auburn University — Expiratory Central Airway Collapse (ECAC), defined by greater than 50% collapse of the trachea during expiration, is a disorder associated with Chronic Obstructive Pulmonary Disease. Pathophysiology of ECAC is multifactorial and the biofluid mechanics of airflow in the trachea could be an important factor resulting in the progression of the disease. Using computational methodology, a comprehensive investigation of the biofluid mechanics in the healthy and diseased patient-specific trachea can be conducted. One of the key considerations for setting up computations is choosing correct boundary conditions (BC). Most common BCs used by previous studies are a) flat, b) parabolic, c) Womersley, d) parabolic with an extension, and e) real, patient-specific profile. This is the first step in that direction to explore the effects of different inlet BCs for patient-specific trachea flow simulations. We test for steady and tidal flow combined with the five aforementioned inlet velocity profile conditions. Metrics such as wall shear stress and time-averaged wall shear stress were used to quantify the differences among different inlet velocity profile condition. This will lay a solid foundation towards obtaining accurate computational results in modeling ECAC.

Saturday, November 23, 2019 3:00PM - 4:31PM —
Session A30 Biological Fluid Dynamics : Micro-Swimmer General I

3:05PM A29.00006 Effect of Cartilaginous Rings in a Model of Human Trachea with Stenosis, HUMBERTO BOCANEGRA EVANS, JOS MONTOYA SEGNNINI, ALI DOOSTTALAB, Purdue University, JOEHASSIN CORDERO, Texas Tech University Health Sciences Center, LUCIANO CASTILLO, Purdue University — The human trachea is structurally supported by a series of cartilaginous rings, which introduce corrugations along the wall surface. Nevertheless, the airway walls are generally considered smooth for respiratory fluid dynamics research purposes. Previous results by Bocanegra Evans and Castillo (J. Biomech., 49, 1601, 2016) demonstrate that these rings have a significant impact on the flow separation found in the tracheobronchial bifurcation. Here, we study the effect that such rings have in a trachea model with stenosis. We present an experimental comparison of smooth and ‘ringed’ models with a grade III (70% blockage) stenotic contraction. Particle image velocimetry measurements are carried out in a refractive index-matching facility simulating resting breathing state conditions (ReD = 3,350). Our results show that cartilaginous rings induce velocity fluctuations in the downstream flow, which enhances the near-wall momentum flux and reduces flow separation after the stenosis. The maximum upstream velocity of the recirculation is reduced by 38% in the model with rings, resulting in a weaker recirculation zone. These results highlight the importance of the cartilaginous rings—and other small features—in respiratory flows.

3:13PM A30.00003 How Azimuthal Swirl Impacts Swimming Kinematics in a Viscoelastic Fluid1, JEREMY P. BINAGIA, Stanford University, ARDELLA PHOA, Santa Clara University, ERIC S. G. SHAQFEH, Stanford University — Microorganisms are often found moving through viscoelastic environments such as mucus layers or biofilms. In 2014, Zhu & Lauga simulated the steady motion of a spherical “squirmmer” in a viscoelastic fluid to understand how fluid elasticity impacts the organism’s speed. The squirmmer considers a spherical swimmer that includes a specified slip velocity at its surface. This model has been used extensively to study the motion of ciliates like Paramecium, colonies of the green algae Volvox, or as a simplified model for general swimmers like E. coli. In all cases, they found that a squirmmer swims slower than it does in a Newtonian fluid. In that study and many others that use the squirmmer model, only the first two axisymmetric swimming modes are considered. Only very recently have authors considered the addition of other modes, such as those that involve azimuthal surface velocities. Recently, we have conducted simulations showing that particular combinations of the axisymmetric swirling modes can actually lead to a speed increase in an elastic fluid. In this talk, we will describe how the inclusion of this azimuthal swirl affects swimming kinematics in elastic fluids, with a focus on how polymer deformation leads to changes in speed.

3:39PM A30.00004 Effective diffusivity of microswimmers in a crowded environment

- MARVIN BRUN-COSME-BRUNY, Grenoble Alpes University — The effect of crowded environments on micro-swimmers is studied using the micro-alga Chlamydomonas Reinhardtii (CR) as a model system. Performing a Run-and-Tumble motion in bulk, its swimming describes a persistent random walk characterized by an effective diffusion coefficient for the large-time dynamics. This swimming is experimentally observed in a complex medium made of series of pillars designed in a regular lattice, using soft lithography microfabrication. Their trajectories are tracked and analyzed. The measure of relevant statistical observables provides insight into the bias induced by the obstacles. Particularly, the mean correlation time of direction and the effective diffusion coefficient are shown to decrease when increasing the density of pillars. This provides some bases of understanding for active matter in complex environments.

3:52PM A30.00005 Modeling helical swimming in shear-thinning fluids

- NOAH LORDI, Santa Clara University, EBRU DEMIR, Beijing Computational Science Research Center, Santa Clara University, YANG DING, Beijing Computational Science Research Center, ON SHUN PAK, Santa Clara University — Swimming bacteria, such as Escherichia coli, propel by rotating their helical flagella with rotary motors in the cell membrane. Helical microswimmers rotated by external magnetic fields have been fabricated to mimic the helical propulsion of bacteria. While helical propulsion has already been extensively studied with the Newtonian fluid assumption, the performance of this propulsion mechanism in non-Newtonian fluids has attracted considerable attention recently. Biological and synthetic microswimmers move through complex fluids that often display shear-thinning viscosity. In this talk, we will discuss a theoretical model to investigate the effect of shear-thinning rheology on helical propulsion. We will highlight the similarities and differences in the propulsion performance in contrast to the results in the Newtonian limit, and compare model predictions with recent experiments on helical propulsion in shear-thinning fluids.

4:05PM A30.00006 Active particles in viscosity gradients

- GWYN ELFRING, CHARU DATT, University of British Columbia — Microswimmers in nature often experience spatial gradients of viscosity. In this work we develop theoretical results for the dynamics of active particles, biological or otherwise, swimming through viscosity gradients. We model the active particles (or microswimmers) using the squirmer model, and show how the effects of viscosity gradients depend on the swimming gait of the swimmers and how viscosity gradients lead to viscotaxis for squirmers. We also show how such gradients in viscosity may be used to sort and control swimmers based on their swimming style.

4:18PM A30.00007 The Dispersal of Swimming Microalgae in Viscosity Gradients

- MICHAEL R. STEHNACH, NICOLAS WAISBORD, JEFFREY S. GUASTO, Tufts University — Swimming cells often live in fluid environments characterized by spatial gradients of rheological properties, including biofilms and mucus layers. However, our understanding of cell transport in such environments is lacking. In this work, we use microfluidic devices to generate a spatial concentration gradient of a Newtonian polymer suspension — thus creating a viscosity gradient. Video microscopy is used to quantify the viscosity landscape and the cell motility. We demonstrate experimentally that swimming biflagellates (wild-type Chlamydomonas reinhardtii) accumulate in high viscosity regions (viscotactic response), stemming from a local reduction in cell swimming speed. A statistical analysis of the cell motility reveals that the viscous slowdown of the microalgae is due to their approximately constant flagellar thrust force in different ambient viscosities. We further demonstrate that this local viscous slowing of cell motility, leading to accumulation, is generalized in highly nonlinear viscosity gradients.

Session A31 Biological Fluid Dynamics: General I

3:00PM A31.00001 Machine learning in cardiovascular flows modeling: Predicting pulse wave propagation from non-invasive clinical measurements using physics-informed deep learning

- GEORGIOS KISSAS, YIBO YANG, EILEEN HWUANG, WALTER WITSCHHEY, JOHN DETRE, PARIS PERDIKARIS, University of Pennsylvania, CORLAB TEAM, PREDICTIVE INTELLIGENCE LAB TEAM — Advances in computational science offer a principled pipeline for predictive modeling of cardiovascular flows and aspire to provide a valuable tool for monitoring, diagnostics & surgical planning. Such models can nowadays be deployed on large patient-specific topologies of systemic arterial networks; but their success heavily relies on tedious pre-processing and calibration procedures that typically induce a significant computational cost. In this work we put forth a physics-informed learning framework that enables the seamless synthesis of non-invasive in-vivo measurement techniques & computational fluid dynamics models derived from first physical principles. We illustrate this new paradigm by showing how one-dimensional models of pulsatile flow can be used to constrain the output of deep neural networks such that their predictions satisfy the conservation of mass and momentum principles. Once trained on noisy and scattered clinical data of flow and wall displacement, these networks can return physically consistent predictions for velocity, pressure and wall displacement pulse wave propagation, and calculate the Windkessel model parameters as a post-processing step.

3:13PM A31.00002 A Simplified Model for the Motion of the Brain Matter in Response to Translational Impacts to the Head

- JI LANG, QIANHONG WU, Villanova University — A simplified mathematical model is developed to simulate the motion of the brain matter as our head is exposed to sudden external impacts. During the process, the cerebrospinal fluid in the subarachnoid space behaves as a squeeze damper to provide protection to the brain matter. The problem involves a solid object bathed in a liquid environment and enclosed in a container. The relative motion of the object to the container causes a squeezing flow on one side of the object and a reverse squeezing flow on the other side. A simplified theoretical model is developed in which both the inner object and the outer container are modeled as cylinders of different sizes. A constant acceleration is imposed on the container. The pressurization of the fluid and the resultant motion of the inner object is analytically predicted and validated using Ansys CFX. The result shows that the relative motion of the inner object is very sensitive to the gap thickness and the density difference between the object and the surrounding liquid. The squeezing damping effect can effectively prevent the direct contact between the solid object and the container.

3:26PM A31.00003 Kinetics of Lactoferrin-Mediated Iron Transport through Blood-Brain Barrier Endothelial Cells. 1, PRASHANTA DUTTA, AMINUL KHAN, JIN LIU, Washington State University — Abnormally high levels of iron have been confirmed in the brain cells during several neuro-diseases such as Parkinson’s, Alzheimer’s etc. Although transferrin-mediated transcytosis is the leading mechanism for iron transport to brain, it has been found that the excessive brain irons are not resulted from transferrin. Instead, lactoferrin (Lf) is a prime suspect because of its abundant availability in the affected regions of brain. However, the kinetics of Lf-mediated iron transport is still unknown. In this paper, a mass-action based kinetic model has been presented to address the transport of Lf-mediated irons through the blood-brain barrier. The kinetic rate parameters of the model are estimated by Bayesian inference method. The robustness of the model is verified by perturbing the estimated parameters. Our results show that an increase in high affinity, but not low affinity, receptors results in higher lactoferrin as well as irons in the brain. The Lf contributes free as well as bound irons to the brain. The absence of a feedback loop such as iron regulatory proteins allows continuous transport of Lf and iron through Lf-mediated pathway, which might raise brain irons and contribute to the neurodegeneration.

3:39PM A31.00004 Microfluidics modeling of interstitial flow through a tumor, BENJAMIN TAY, MARCOS MARCOS, Nanyang Technological University, DAVID GONZALEZ-RODRIGUEZ, Université de Lorraine — 90% of cancer-related mortalities are due to metastasis. Interstitial pressure and flow within tumor microenvironment have been identified to influence biological and biochemical aspects of metastasis. However, little is known on the biophysical effect. This study focuses on the effect of interstitial pressure and flow on the detachment of tumor cells from primary tumor. Interstitial flow through a tumor generates tensile force in the direction of flow which might contribute to detachment of tumor cells from primary tumor. Here, flow is introduced into a microfluidic device to measure pressure difference across MCF-7 aggregates with different adhesions. Aggregates with different adhesions mimic in-vivo heterogeneous tumor. Initially, fluid seeps through the porous aggregate. As pressure builds up at the afferent end, pressure-driven flow through the aggregate increases. At critical pressure difference, fracture occurs and hydraulic permeability increases. Cell masses dislodge from aggregate. Fractures occur at different critical pressure for aggregates with different adhesions. This mimic the detachment of tumor cells from primary tumor. These findings will provide better understanding about the biophysical effects of interstitial pressure and flow.

The author’s full name is Marcos.

3:52PM A31.00005 Fluid exchange dynamics during respiratory-type flows, ERIN CONNOR, AARON TRUE, MELANIE HOLLAND, JOHN CRIMALDI, University of Colorado, Boulder — Respiratory-type flows occur across a large range of scales in natural and engineered environments. These flows, characterized by the cyclic inhale and exhale of a fixed fluid volume through an orifice, result in dynamic spatiotemporal flow interactions even in quiescent surroundings. We use numerical and experimental approaches to investigate simple respiratory-type flows at scales relevant to biological sensory and metabolic processes. Organisms successfully gain access to scalars in the fluid when the amount of exhaled fluid that is subsequently re-inhaled (exchange ratio, r_E) is small. This study focuses on this exchange of fluid, whereas studies of other similar flows with ‘net-zero mass flux’ (e.g., synthetic jets) often emphasize the transport of momentum. Using time-resolved flow fields to map the Lagrangian histories of inhale and exhale cycles, we demonstrate that r_E is sensitive to small changes in Reynolds number (Re). We show that this sensitivity is due to asymmetries in the inhale and exhale flow structures; these asymmetries vanish only in the limit as Re approaches zero. We also demonstrate that r_E is sensitive to the I:E ratio, defined as the ratio of inhalation time to exhalation time. Our results suggest that organisms could optimize the exchange of fluids with their environment by modulating Re or I:E ratio.

4:05PM A31.00006 Starting jet formation through eversion of flexible plates, CHEOLGYUN JUNG, DAEGYOUM KIM, KAIST — A starting jet found in nature, such as flow through heart valves or jet propulsion of aquatic animals, is generated by the interaction of pressurized fluid with deformable membranes. The starting jet can also be formed by the interaction of pressurized fluid with deformable membranes. For example, the nematocysts of the Cnidarian animals, is generated by the interaction of pressurized fluid with deformable membranes. The starting jet flow through eversion process using a simplified model that represents an everted structure. The ends of two everted flexible plates with a large aspect ratio are clamped at both sides of a rectangular channel, and the other ends of them are in contact with each other in the middle of the channel to model the everted structure. With this configuration, we study the eversion dynamics of the flexible plates and the formation of jet flow at the exit of the channel.

4:18PM A31.00007 Acceleration-induced water ejection in the human ear canal, ANUJ BASKOTA, SEUNGHO KIM, Cornell University, HOSUNG KANG, Virginia Tech, SUNGHWAN JUNG, Cornell University — Water entering the ear canal is a common problem during swimming, showering or other water sports. The trapped water can lead to an ear infection as well as damage to the ear canal. A common strategy for emptying water from the ear canal is to shake the head, where the force created due to the head jerk helps push the water out. One-end closed hydrophobic glass tubes of varying diameters were used as a simplified model of the ear canal. Then, the tube is dropped onto a spring to mimic the shaking strategy. Results revealed that the critical acceleration to remove the water from the ear canal strongly depends on the volume and the position of trapped liquid inside the tube. We found that the critical acceleration is on the order of 10 g, which may cause serious damage to the human brain. The critical acceleration tends to be much higher in smaller sized tubes which indicates that shaking heads for water removal can be more laborious to children due to their small size of the ear canal, compared to adults.
3:00PM A32.00001 Boundary integral simulations of a red blood cell squeezing through a submicron slit under prescribed inlet and outlet pressures. ZHANGLI PENG, HUIJIE LU, University of Notre Dame, ALEXIS MOREAU, EMMANUELLE HELFER, ANNE CHARRIER, ANNIE VIALLAT, CNRS Aix Marseille University, France — We developed a boundary integral formulation to simulate a red blood cell (RBC) squeezing through a submicron slit under prescribed inlet and outlet pressures. The main application of this computational study is to investigate splenic filtrations of RBCs and the corresponding in vitro mimicking microfluidic devices, during which RBCs regularly pass through inter-endothelial slits with a width less than 1.0 micrometer. The diseased and old RBCs are damaged or destroyed in this mechanical filtration process. We first derived the boundary integral equations of a RBC immersed in a confined domain with prescribed inlet and outlet pressures. A multiscale model is applied to calculate forces from the RBC membrane, and it is coupled to boundary integral equations to simulate the fluid-structure interaction. After multi-step verifications and validations against analytical and experimental results, we systematically investigated the effects of pressure drop, volume-to-surface-area ratio, internal viscosity, and membrane stiffness on RBC deformation and internal stress. We found that spectrins of RBCs could be stretched by more than 2.5 times under high hydrodynamic pressure and that the bilayer tension could be more than 500 pN/um, which might be large enough to open mecanosensitive channels but too small to rupture the bilayer. On the other hand, we found that the bilayer-cytoskeletal dissociation stress is too low to induce bilayer vesiculation. This project is partially supported by NSF Grant CBET-1706436.

3:13PM A32.00002 Fluid-Structure Interaction of Bioluminescence. MAZIYAR JALAA, NICO SCHRAMMA, RAYMOND GOLDSSTEIN, DAMTP, University of Cambridge — Bioluminescence (emission of light from living organisms) is a common form of communication in the ocean. Here we study the bioluminescence on a single-cell level, aiming to understand the response to mechanical stimulation. In our experiments, the cell (an alga) was immobilised via micro-pipette aspiration. We impose pressure on the cell, via a submerged impinging jet. We show that the flow-induced stress on the cell membrane results in a local elastic deformation. As a result, a series of chemical signaling events occur that eventually yields to light production in sub-cellular compartments. Besides experiments, we propose a counterpart model.

3:26PM A32.00003 Flow-Induced Deformation of Cells During Small Opening Traversal. IGOR V. PIVKIN, Institute of Computational Science, USI Lugano, Switzerland — We performed experimental and computational study of cells in microfluidics measuring cell traversal through the series of openings of various sizes. MCF-10A, MCF-7 and MDA-MB-231 cells were used in experiments and corresponding computational models were developed using particle-based approach. Deformability of cells under the flow conditions will be discussed. This work was done in collaboration with the group of Chwee Teck Lim from National University of Singapore.

3:39PM A32.00004 Deformation and viability of an encapsulated cell through a microfluidic contraction. MOHAMMAD NOORANIDOOST, RANGANATHAN KUMAR, University of Central Florida — Deformation and viability of an encapsulated cell moving through a sudden contraction in a capillary tube is studied using a front-tracking method. A cell-laden droplet is initiated in a capillary tube which is allowed to migrate with the flow. When it moves through a sudden contraction, high shear stresses are experienced around the droplet where the velocity is maximum. The interplay between these stresses and interfacial forces, as well as the geometrical constraint squeezes the droplet resulting in the deformation of the inner cell. A cell viability model is used to relate the cell deformation to cell viability. Deformation and viability of the cell are highly dependent on encapsulating droplet properties and the geometry of the contraction. For a fixed geometry of the contraction, viscosity and size of the encapsulating droplet can be adjusted to minimize cell deformation. Increasing droplet size for low viscosity of the droplet shell helps reduce the deformation and maintain the viability of the cells. The deformation is enhanced for capillary tubes with narrow and long contractions, which leads to a lower cell viability. This study can be useful in biomedical applications to improve viability of cells migrating in channels with sudden obstacles.

3:52PM A32.00005 Effect of constitutive laws on erythrocyte membrane response. MARIANNA PEPONA, Duke University, JOHN GOUNLEY, Oak Ridge National Laboratory, AMANDA RANDLES, Duke University — Despite the extensive literature on the modelling of red blood cells, only a few works have compared the response of a deforming red blood cell to different constitutive laws. In the current work, three different constitutive equations are considered: the strain-hardening Skalaks law, the strain-softening neo-Hookean model, and Yeohs law, whose nature and degree of strain-hardening/softening depend on the deformation regime and type. The performance of these laws is assessed on accurately capturing deformations in the longitudinal and transverse directions, and under shear via optical tweezers, micropipette aspiration and wheel numerical experiments, respectively. Particular emphasis is given to the nonlinear deformation regime, i.e. moderate and large deformations, where it is known that the discrepancies between various constitutive laws are most prominent. Finally, we compare the aforementioned laws in the configuration of a single red blood cell flowing inside a capillary. This work aims at providing criteria for selecting the constitutive law best describing the erythrocyte membrane mechanics for the deformation type and regime of interest.

4:05PM A32.00006 Shake, rattle, and roll: microstreaming flows from acoustically oscillating cells. SCOTT TSAI, ALINAGHI SALARI, SILA APPAK-BASKOY, MICHAEL KOLIOS, Ryerson University — Steady-state microstreaming flows can arise from the interaction of sound waves with elastic objects, such as bubbles. Such microstreaming finds utility in cell and particle manipulation, and in microfluidic pumping and analyte mixing. Here, we describe a new observation that in vitro single cells that are excited by a controlled acoustic wave are also able to generate microstreaming flows. Specifically, adherent cells under the influence of a surface acoustic wave oscillate inside a microfluidic channel to generate microstreaming flows. We study the cellular properties that affect the degree of microstreaming by, for example, imposing an osmotic shock to the cell, manipulating the cell structure enzymatically using trypsin, and chemically, using paraformaldehyde and Cytochalasin D. Our findings suggest that the microstreaming induced by MDA-MB-231 cells is primarily controlled by the overall cell stiffness. We thus conclude that measuring the resulting flow pattern and velocity magnitude may be utilized as a label-free proxy for quantifying the mechanical properties, such as stiffness, of the cell.

This work is supported by the Canadian Natural Sciences and Engineering Research Council (NSERC; No. STGP 506318 & RGPIN-2017-06496). Equipment funding is from Ryerson University, the Canada Foundation for Innovation (CFI), and the Ontario Research Fund (ORF).
4:18PM A32.00007 A Microfluidic Platform for the Study of Cell Deformability

AMIR SAADAT, DIEGO A. HUYKE, INGRID H. OVREEIDE, DIEGO I. OYARZUN, Stanford University, PAULINA V. ESCOBAR, Pontificia Universidad Católica de Chile, JUAN G. SANTIAGO, ERIC S. G. SHAQFEH, Stanford University, SHAQFEH TEAM, SANTIAGO TEAM — Reduced deformability of red blood cells (RBCs) can affect the hemodynamics in the microcirculation and reduce the oxygen transport efficiency. To this end, we developed a high-fidelity computational model of RBCs in confined microchannels to inform design decisions and fabricate a microfluidic device to measure RBC deformability. We applied our computational simulation platform to determine the appropriate deformability figure(s) of merit to quantify RBC stiffness based on an experimentally measured, steady cell shape. In particular, we determined a shape parameter based on the moment of area that is sensitive to the changes in the membrane stiffness and size. We conducted experiments and developed automatic image processing codes to track the velocity and morphology of individual RBCs within microchannels. For this purpose, we fabricated PDMS microchannels with square cross-sections (7x7 μm<sup>2</sup>) and applied a small (order 10 kPa) gauge pressure at the inlet to induce cell movement (order 10 μm s<sup>−1</sup>). Our experimental setup can record 200 cells per second, and achieve image exposure times on the order of 10 μs. This microfluidic device and supporting computational tools are intended to diagnose blood cell disorders in chronic fatigue syndrome (CFS) patients relative to the healthy controls.

Session A33 Flow Instability: Richtmyer-Meshkov

3:00PM A33.00001 Characterization of Rapid Solid-Particle Dispersal by a Blast Wave

BERTRAND ROLLIN, Embry-Riddle Aeronautical University, RAHUL KONERU, BRADFORD DURANT, FREDERICK OUELLET, University of Florida — The impulsive dispersal of a bed of solid particles is often accompanied by the late time formation of coherent aerodynamic structures identified as particle jets. Despite numerous experimental and numerical studies to date, the intricate mechanisms leading to the formation and selection of these jets have not been conclusively characterized. In light of recently published experimental work, numerical simulations of the performed using the quasi-two-dimensional geometric setting of a Hele-Shaw cell. Explicitly, a dense and uniform volumetric distribution of solid particles shaped in the form of a right circular hollow cylinder is sandwiched between two solid plates separated by a small distance. The initial impulse to the particles is then given by a relatively weak air blast wave. The highly resolved point-particle simulations focus on the interplay between particle inertia and the gas-solid particle limit of classic hydrodynamic instabilities such as the Rayleigh-Taylor and the Richtmyer-Meshkov instabilities, in explaining the formation of internal and external particle jets. The initial overpressure and particle properties are used as control parameters in the quantification of the characteristics of the late-time particle jets.

3:13PM A33.00002 Attenuation of transmitted shock by a particle-seeded layer

PETER VOROBIEFF, University of New Mexico, GUSTAAF JACOBS, TZ-TING HUNG, San Diego State University — We conduct an experimental and numerical study of a nominally planar interaction of a normal shock with a layer of particles embedded in gas (air). Prior experimental studies reveal that even a particle layer with a modest volume fraction of particles (1-9%) produces a reflected pressure wave at Mach numbers above 1.4. The present work focuses on two aspects of the flow. First, we examine the transmitted pressure wave, using both experimental measurements and computational modeling, and seek to identify the influence of the system used to form the particle layer in experiments and any effects peculiar to the layer thickness. Second, we present a simple model describing perturbation growth in the gravity-driven particle layer before the shock arrival.

1This research is supported by NSF grant 1603915.

3:26PM A33.00003 Acceleration of a Vortex Ring-Deformed Stratified Interface by a Planar Shock Wave

ALEX AMES, UW-Madison, CHRIS WEBER, Lawrence Livermore National Laboratory — Vortices are a well-known mechanism of transport across stratified interfaces. When repeatedly shocked, preexisting vorticity-driven deformation of the interface provides greater leverage for baroclinic torque under subsequent acceleration. The locally axisymmetric baroclinic vorticity deposition is a primary source in the turbulent energy cascade, leading to anisotropically-oriented eddies at the inertial scale, producing deleterious interfacial mixing. In particular, the assembly of a uniform fusion hotspot in inertial confinement fusion capsules is disrupted by the protrusion of a cold vortical bubble arising from the remains of the fill tube. The morphology and evolution of compressible, variable-density vortices upon shock acceleration is explored computationally using the MIRANDA hydrodynamics code. A laboratory-scale configuration comprising a vortex ring discharged upwards into a stably-stratified layer from the open end of a small shock tube is compared for hydrodynamic similarity to a representative ICF fill tube perturbation. Vortex evolution, baroclinic production during and following shock interaction, behavior of secondary vortices, and mixing intensification are detailed across a range of vortex strengths and Atwood & Mach numbers.

3:39PM A33.00004 The effect of membraneless initial conditions on the growth of Richtmyer-Meshkov instability.

MOHAMMAD MANSOOR, SEAN DALTON, ADAM MARTINEZ, TIFFANY DESJARDINS, JOHN CHARONKO, KATHY PRESTRIDGE, Los Alamos National Laboratory, EXTREME FLUIDS TEAM — The Richtmyer-Meshkov Instability (RMI) is described by the baroclinic generation of vorticity at a density stratified interface when impulsively accelerated. Here, we experimentally investigate the late-time RMI growth of sinusuous perturbations of an air/sulfur hexafluoride interface subjected to a Mach 1.2 planar shock wave within the vertical shock tube (VST) facility at Los Alamos National Laboratory. Interface perturbations are established using a novel membraneless technique where cross-flowing Air and SF6 separated by oscillating splitter plate enter the shock tube with an undulating structure. It is found that late-time perturbation growth behavior depends significantly on initial perturbation wavelength and peak-to-valley amplitude as prescribed by the frequency and sweeping angles of the “oscillating plate”. The results are compared with past nonlinear models for various scaled initial amplitudes (ka<sub>0</sub>) and used to propose an empirical rational function that captures the asymptotic behavior of perturbation growth for both low and high scaled initial amplitudes.
3:52PM A33.00005 Time-Resolved Particle Image Velocimetry of the 3-D, Multi-Mode Richtmyer-Meshkov Instability. JEFFREY JACOBS, EVEREST SEWELL, KEVIN FERGUSON. The University of Arizona — We present recent experiments conducted on the multi-mode Richtmyer-Meshkov instability (RMI) using time-resolved Particle Image Velocimetry (PIV), comparing results initiated using high and low amplitude initial perturbations. Measurements of the growth parameter $\theta$ indicate a slight difference in growth rate exists between the two groups following the incident shock interaction, with additional differences in the growth of the instability following reshock. We validate a novel method of obtaining $\theta$ from the decay of turbulent kinetic energy (Thorburn et al., J. Fluid Mech., 2010). Examination of the anisotropy ratio reveals an asymptotic value of approximately 1.8 in high amplitude experiments, while low amplitude experiments exhibit decreasing anisotropy. High amplitude experiments exhibit an inertial range, while low amplitude experiments remain below the threshold for inertial range for most times. An extension of this analysis for developing flows (Zhou et al., Phys Rev E, 2003) reveals that neither flow satisfies the extended transition (Dimotakis, J. Fluid Mech., 2000) following the incident shock, with low amplitude experiments remaining below the threshold for mixing transition. This observation is supported by the lack of an apparent inertial range in the power spectra of velocity.

4:05PM A33.00006 Scalar Power spectrum and Structure Function analysis of the Richtmyer-Meshkov Instability Upon Re-Shock$^1$. CHRISTOPHER NOBLE, JOSHUA HERZOG, ALEX AMES, JASON OAKLEY, DAVID ROTHAMER, RICCARDO BONAZZA, University of Wisconsin - Madison — The Richtmyer-Meshkov instability of a twice-shocked gas interface is investigated in the vertical shock tube of the Wisconsin Shock Tube Laboratory at the University of Wisconsin–Madison. The initial condition is a shear layer, containing broadband perturbations, formed at the interface between a helium-acetone mixture and argon. The interface is accelerated with a shock of nominal strength $M=1.9$ with an initial Atwood number of $A=0.43$. Acetone is used as a molecular tracer for PLIF, allowing the extraction of concentration data by using a pulse burst laser system at 20kHz to excite acetone to fluoresce. The resulting fluorescence signal is measured using a high-speed Phantom camera. The evolution of the scalar power spectrum is investigated. As seen in previous single shock experiments a region of -5/3 slope is seen at late post-shock times, however at late re-shock times a larger region of -8/3 spectrum is observed. The measurement limit of the present experiments is estimated to be within the inertial range that may exist thus the measured slope is not expected to be a dissipation effect but the slope of the inertial range. Scalar structure functions are calculated, with the anomalous exponent being plotted against the structure function order also showing a non-KOC scaling. The terms in the scalar power spectrum evolution equation are calculated showing an asymmetry about the centre of the mixing layer and suggesting the emergence of an inertial range.

4:18PM A33.00007 High-resolution, time-resolved PIV measurements on the Richtmyer-Meshkov instability in a dual-driver vertical shock tube. KEVIN FERGUSON, EVEREST SEWELL, JEFFREY JACOBS, The University of Arizona — Experiments on the Richtmyer-Meshkov Instability (RMI) using Particle Image Velocimetry (PIV) in a dual driver vertical shock tube are presented. Two shock waves generated at opposite ends of a vertical shock tube travel in opposing directions, impacting a perturbed interface formed between Air and Sulfur Hexafluoride ($\text{SF}_6$). Perturbations are formed using a pair of voice coil driven pistons that generate Faraday waves on the interface. The incident shock wave arrives from the air side of the interface which initiates the RMI. Shortly afterward a second shock wave arrives from the $\text{SF}_6$ side which generates reshock. Shock strengths are chosen to result in halfed interface motion after passage of the second shock wave, permitting a long observational window in which the instability can evolve and yielding a simplified optical and recording setup as compared to typical single-driver experiments. Four cameras are utilized in a tiled pattern to create a high-speed recording of each experiment with a greatly increased final vector resolution compared to previous experiments. Information on the growth of the RMI, including measurements of the growth exponent, $\theta$, anisotropy, and turbulent kinetic energy decay are presented.

Saturday, November 23, 2019 3:00PM - 4:31PM — Session A34 Flow Instability: Transition to Turbulence 616 - Jae Sung Park, UNL

3:00PM A34.00001 Transition in Pulsatile Flows with Flow Reversals$^1$. JOAN GOMEZ, YIANNIS ANDREPOULOS, City College of New York, YIANNIS ANDREPOULOS TEAM — Pulsatile flows are of interest because for certain range of Reynolds and Womersley numbers they exhibit flow reversals while at the same time they display laminar and turbulent behavior at different times of the pulsating cycle. Addressing how turbulence appears, decays and is suppressed in such environments is challenging due to the flow unsteadiness and flow-wall interactions. An experiment was setup to replicate pulsatile motion of water flowing in a clear, rigid pipe. The flow is driven by a piston-motor assembly controlled by a computer to induce cyclic motion of the mean flow. Time-Resolved Particle Image Velocimetry (TR-PIV) techniques are used to acquire velocity data on the plane of a CW laser illumination sheet. Simultaneous acquisition of time-dependent PIV data and wall pressure measurements, obtained from pressure sensors installed along the length of the pipe, allow the estimation of the instantaneous wall shear-stress which was used as a metric for the appearance of reverse and forward flow regions. It was found that the reverse flow region is formed close to the wall and it is bounded from the forward flow region by a counter-flowing shear-layer. Transition to turbulence occurs within this shear layer which prevents propagation of disturbances from the near wall region towards the center of the pipe.

3:13PM A34.00002 The impact of slip surfaces on exact coherent states: insight into the transition-to-turbulence$^1$. ETHAN DAVIS, JAE SUNG PARK, University of Nebraska-Lincoln — The effect of slip surfaces on the laminar-turbulent separatrix, or transition, in a channel geometry is studied by direct numerical simulation. Firstly, turbulence lifetimes, or the likelihood that turbulence persists, is investigated. Slip surfaces decrease the likelihood of sustained turbulence. The likelihood is decreased further with increasing slip length. Secondly, a more deterministic approach is used to investigate the effect of slip surfaces on the transition to turbulence. To this end, exact coherent states, specifically nonlinear traveling wave solutions to the Navier-Stokes equations, are used as initial conditions. Lower-branch solutions are insightful for the study of transition as they lie along the laminar-turbulent boundary in state-space. Two solution families, P3 (core mode) and P4 (critical layer mode), are considered. For P3, slip surfaces delay the transition, whereas for P4, viscosity is the primary mechanism. In general, slip surfaces delay the transition while weakening the instability. Beyond a critical slip length, the instability is totally eliminated, and flow is laminarized. Flow dynamics and structures are further discussed for this transition events.

of wild type cells and a mutant lacking flagella, suggesting that CO

Cholerae 1800 (Schlichting jet) or use 2D perturbations, which do not allow for spanwise variation (Bickley jet). The 3D normal modes are then investigated of the Schlichting jet and its planar counterpart, the Bickley jet, most of which, to our knowledge, either require perturbations to be axisymmetric three-dimensional (3D) normal-mode perturbations to the 2D base flow. We compare our results to previously published linear stability analyses of the Schlichting jet and its planar counterpart, the Bickley jet, most of which, to our knowledge, either require perturbations to be axisymmetric or use 2D perturbations, which do not allow for spanwise variation (Bickley jet). The 3D normal modes are then investigated using DNS to understand the nonlinear saturation (in the sense of growth and maximization of perturbation energy) and the transition of the flow to a fully turbulent state.

Spatial amplification of coupled disturbances in bluff body shear layers, DANIEL MOORE, MICHAEL AMITAY, Rensselaer Polytechnic Institute — Detailed experimental campaigns into separated shear layers have been carried out on a series of rectangular sections over a Reynolds number range from 13,400 to 118,000, based on the body height, at a range of angles of attack. Recent work by this same group has demonstrated the level of coupling that occurs between the convective shear layer instability at the leading and the global, large-scale instability associated with wake shedding of these sharp-edged rectangular sections. Building upon these findings, the spatial amplification of the separated shear layers is experimentally derived and compared to other shear flows including the classical planar mixing layer. Results show that the effect of a coupled shear layer manifests itself via a relatively broad spectrum of unstable frequencies and significantly elevated growth rates. On the other hand, reducing the coupling the same two instabilities has the opposite effect. It is further shown that the coupling is directly tied to a turbulent transition length, reinforcing the notion of a globally unstable flow field.

Temporal development of hairpin vortex sequences in turbulent puffs, KYLE WINTERS, ELLEN LONGMIRE, University of Minnesota, DEPARTMENT OF AEROSPACE ENGINEERING AND MECHANICS TEAM — Puffs are characterized by intermittent swirling structures that develop from sufficient perturbations to pipe flow around 1800 < Re < 7000. By conducting stereo-PIV on circular cross sections, the authors examined hairpin-shaped vortices near the trailing edge of many puffs. To study the temporal evolution of the hairpins, planar-PIV was conducted on an axial-wall normal plane inside a 44.8 mm diameter, D, 8.8m (180D) downstream of a disturbance ring. In certain records, the measurement plane coincided with the plane of symmetry of a hairpin. This allowed for comparison with the stereo-PIV records and examination of the hairpin development. The hairpin heads and associated velocity fluctuations grew in strength as they moved both downstream and away from the wall. Eventually the original hairpin spawned a new hairpin upstream close to the wall at the same azimuthal position. The axial spacing between the two hairpins agreed with that observed in the stereo-PIV records. Further, the spacing grew as they continued to propagate downstream at velocities that generally agree with the propagation of axial fluctuations noted by Shimizu and Kida (2008). The overall development process was similar to that outlined by Jodai and Elsinga (2016) in a turbulent boundary layer.

The onset of turbulence in channel flow, BJORN HOF, VASUDEVAN MUKUND, CHAITANYA PARANJAPE, PHILIP SITTE, Institute of Science and Technology Austria — In channel flow turbulence arises at Reynolds numbers where the laminar state is linearly stable and in order to do so the critical point where turbulence first becomes sustained we identify the growth and decay processes of individual turbulent stripes in experiments. As shown, the critical point is reached when the (continuous) entrainment of laminar fluid at the stripes downstream tip outweighs the (stochastic) shedding of turbulence at their upstream tip. For growing stripes, the probability to collapse decreases while the probability to split increases in time. Consequently, neither collapse nor splitting are memoryless and unlike in pipes and unlike in directed percolation, the contamination rate changes in time. The coupling between the growth of individual stripes and the creation of new stripes leads to a significantly lower critical point than most earlier studies suggest.

Saturday, November 23, 2019 3:00PM - 4:31PM — Session A35 Electrokinetic Flows: General 617 - Michael Booty, NJIT

CO₂-driven diffusiophoresis: motion of charged particles near CO₂ dissolving boundaries, SUIN SHIM, Princeton University, OREST SHARDT, University of Limerick, SEPIDEH KHO-DAPARAST, Imperial College London, CHING-YAO LAI, Columbia University, JESSE T. AULT, Brown University, BHARGAV RALLABANDI, University of California, Riverside, HOWARD A. STONE, Princeton University — We present experimental and theoretical investigations for CO₂-driven diffusiophoresis of charged particles. An aqueous suspension of charged particles initially in contact with a CO₂ dissolving interface shows directional migration either up or down the concentration gradient, depending on the particle charges. We use a cylindrical CO₂ bubble in a circular Hele-Shaw cell to study the behavior of polystyrene particles. By experiments and numerical model calculations considering multicomponent gas dissolution, we prove the diffusiophoretic accumulation and exclusion of particles near the bubble interface. Then using two geometrical conditions with moving and fixed boundaries, we show diffusiophoresis of bacterial cells driven by dissolution of CO₂. Vibrio Cholerae, a Gram-negative bacteria, has a negative surface charge and thus migrates away from a CO₂ source. Using PIV we show behaviors of wild type cells and a mutant lacking flagella, suggesting that CO₂-driven diffusiophoresis may prevent biofilm formation by reducing the population of cells approaching an interface.

We acknowledge the NSF for support via grant CBET-1702693.

AC Electrokinetics in the Limits of Extremely High Voltage and Ion-Asymmetry, ARUNRAJ BALAJI, SHAHAB MRJALILI, ALI MANI, Stanford University — The aim of this study is to extend understanding of AC electrokinetics to regimes involving Dielectric Barrier Discharge (DBD) plasmas. To this end, we consider a simple model utilizing the Poisson-Navier-Planck and Navier-Stokes equations, as commonly used in analysis of electrokinetic phenomena. To study the specific regimes relevant to plasmas, we consider the limits of extremely high AC voltage (\( V = O(10^4 V_o) \)) and extremely high ion-asymmetry (\( \frac{\epsilon_{\text{ion}}}{\epsilon_{\text{water}}} = O(10^4) \)). Direct numerical simulation (DNS) of the governing equations is performed in one- and two-dimensional spatial domains, and different regimes of response are identified in terms of input voltage and diffusion asymmetry parameters. In addition to the results of DNS, this work also focuses on modeling considerations for the plasma regime and steps toward a more complete simulation of DBD: one that includes the effects of thermal-nonequilibrium and reactions.

3:26PM A35.00003 A model for electrokinetic flow with deformable interfaces, MICHAEL BOOTY, New Jersey Institute of Technology, MANMAN MA, Tongji University, Shanghai, MICHAEL SIEGEL, New Jersey Institute of Technology — A hybrid or multiscale model is introduced to describe the evolution of a drop in the two-phase flow of immiscible, ionic fluid electrolytes that are driven by an electric field. It is formed from the PNP equations in the Stokes flow regime in the limit when the Debye layers are thin relative to the undeformed drop size. For arbitrary deformation, the model consists of boundary integral equations for the electrostatic potential and the interface fluid velocity together with relations that contain the coupling between the electrostatic and fluid fields within the thin Debye layers. The results of sample numerical simulations are presented, together with comparison to a small-deformation analysis in the limit of a weak applied field; further generalizations of the model are also discussed.

3:39PM A35.00004 Characterization of surface-solute interactions by diffusioosmosis, JESSE AULT, Brown University, SANGWOO SHIN, University of Hawaii at Manoa, HOWARD STONE, Princeton University — The measurement of wall zeta potentials and solute-surface interaction length scales for electrolyte and non-electrolyte solutes, respectively, is critical to the design of biomedical and microfluidic applications. We present a microfluidic approach using diffusioosmosis for measuring either the zeta potentials or characteristic interaction length scales for surfaces exposed to, respectively, electrolyte or non-electrolyte solutes. When flows containing different solute concentrations merge in a junction, local solute concentration gradients can drive diffusioosmosis due to interactions between the solute molecules and solid surfaces. We demonstrate a microfluidic system in which solute concentration gradients drive diffusioosmosis within a pore, resulting in predictable fluid and solute profiles. Furthermore, we present analytical results and a methodology to determine the zeta potential or interaction length scale for the pore surfaces in the system. We apply this method to the experimental data of Lee et al., and we use 3D numerical simulations to validate the theory. To the best of our knowledge this is the first flow-based approach to characterize surface/solute interactions with non-electrolyte solutes.

3:52PM A35.00005 ABSTRACT WITHDRAWN

4:05PM A35.00006 Microscale Electrodeionization: in situ Concentration Profiling and Flow Visualization, SUDONG PARK, RHOKYUN KWAK, Hanyang University, Korea — Electrodeionization (EDI) is a membrane-based desalination system utilizing ion exchange membranes and resins. By combining electrodialysis and ion exchanger, EDI can produce ultrapure water in continuous-flow manner. Although its theoretical mechanisms are well documented, there is no experimental platform which can provide microscopic details inside the system. In this paper, we present microscale EDI that visualizes in situ ion concentration, pH, and fluid flow. The platform was fabricated by filling ion exchange resins as a monolayer in a transparent polydimethylsiloxane channel between cation/anion exchange membranes. According to operating voltages (0-15V), distinct behaviors of ion concentration profile, pH shift, and fluid flow were observed: ohmic, limiting, and overlimiting regimes. It is noteworthy that overlimiting regimes can be sub-categorized as water-splitting regime and electroconvection regime. In early stage (4-6V), water-splitting is dominant with pH change near the membranes and resins; under higher voltage (8-15V), electroconvection start to occur even water-splitting tries to suppress the development of the electroconvective instability on the resins.

4:18PM A35.00007 Non-isothermal electrokinetic effects in an electro-osmotic flow, EDGAR RAMOS, FEDERICO MENDEZ, National Autonomous University of Mexico, JOSE LIZARDI, College of Science and Technology — In this work, we study numerically the combined influence of some non-isothermal electrokinetics effects derived from a Debye length versus fluid viscosity, when both depend on the temperature for an electroosmotic laminar flow circulating in a slit microchannel. Considering then that the Debye length depends on temperature T, together with the fluid viscosity, we obtain additional temperature gradients along the microchannel and the isothermal hypothesis is no longer valid. Therefore, the Navier-Stokes equations together with the energy, Poisson and Ohmic current conservation equations are solved by using a routine finite element method. For this purpose, the governing equations are written in a dimensionless format and we introduce a dimensionless thermal parameter α that measures the temperature deviations of a reference temperature and a dimensionless parameter γ, which defines the effects of the variable viscosity. The numerical predictions show that the influence of these parameters yields different regimes for the behavior of the volumetric flow rate in comparison with a uniform Debye length and strong induced pressure gradients are sensibly altered by the existence of these dimensionless parameters.

Session A36 Microscale Flows: Assembly and Fabrication 618 - Boris Stoerber, University of British Columbia

3:00PM A36.00001 Colloidal particle dynamics during band assembly, ANDREW YEE, MINAMI YODA, Georgia Institute of Technology — Evanescent-wave visualizations have shown that colloidal polystyrene particles in a dilute (volume fractions < 4 × 10^{-3}) suspension assemble into structures called “bands” that only exist near the walls in combined Poiseuille and electroosmotic “counterflow” through silica and polydimethylsiloxane-silica microchannels. These bands have cross-sectional dimensions of a few μm and a length comparable to that of the channel of a few cm. Two-color experiments, where ~1% of the α = 250 nm particles are labeled with a different fluorophore, are used to investigate particle dynamics over time for a range of flow conditions. In the initial accumulation stage, the near-wall particle concentration increases sharply, and continues to increase after the first band is observed, before decreasing to a roughly constant value with a stable number of “steady-state” bands. Although the particles appear to be in a liquid state within these structures, they do not follow the flow, even before the bands form, and have negligible cross-stream motion. The velocities of near-wall particles within the steady-state bands are found to be much less than those between the bands.

3:13PM A36.00002 Solvent-phase electrodeposition of highly concentrated, vertically aligned carbon nanotubes for scalable fabrication of carbon-nanotube membranes. RICHARD CASTELLANO, Rutgers University, ERIC MESHOT, FRANCESCO FORNASIERO, Lawrence Livermore National Labs, ROBERT PRAINO, Chasm Technologies, JERRY SHAN, Rutgers University — Membranes incorporating vertically aligned carbon nanotubes (VA-CNTs) as through-pores have been shown to transport fluids at rates orders-of-magnitude faster than predicted by theory, offering promise as highly permeable membranes for applications as diverse as protective yet breathable garments, and desalination membranes. There is a need for cost-effective and scalable methods for fabricating VA-CNT membranes. Here, we describe a solution-based fabrication technique for VA-CNT membranes using electric-field alignment and electrophoretic concentration of CNTs initially dispersed in a solvent. The quality of electrodeposition is described in terms of the resulting CNT number density. Multiple rounds of solvent-phase CNT alignment and deposition are performed, before the solvent is finally replaced with a UV-curable prepolymer, all while an electric field is applied to preserve CNT alignment. The liquid prepolymer is cured to form membranes, which are shown to have open CNT pores with flow enhancement. We compare the solution-fabricated VA-CNT membranes to those fabricated by other, less-scalable methods, and discuss the implications for large-scale production of such membranes.

3:26PM A36.00003 Multiphase modeling of precipitation-induced membrane formation1, PATRICK EASTHAM, NICK MOORE, NICK COGAN, Department of Mathematics, Florida State University, QINGPU WANG, OLIVER STEINBOCK, Department of Chemistry and Biochemistry, Florida State University — We have formulated a model for the dynamic growth of a membrane developing in a flow as the result of a precipitation reaction, a situation inspired by recent microfluidic experiments. A key challenge is that the location of the immobile membrane is unknown a priori. To model this situation, we use a multiphase framework with fluid and membrane phases; the aqueous chemicals exist as scalar fields that react within the fluid to induce phase change. Analysis demonstrates no-slip behavior on the developing membrane without a priori assumptions on its location, with additional numerical simulation in 2D microfluidic geometries. The model has applications towards precipitate reactions where the precipitate greatly affects the surrounding flow, a situation appearing in many laboratory and geophysical contexts. More generally, this model can be used to address fluid-structure interaction problems that feature the dynamic generation of structures.

3:39PM A36.00004 Dynamic elastocapillarity of hairy tubes. JONGHYUN HA, KAIYING JIANG, SAMEH TAWFICK, University of Illinois at Urbana-Champaign — Elastocapillarity, which is the capillary-driven deformation of slender materials, can be mundanely observed in our daily lives, such as painting, washing the hair, wet grass or leaves. Here, we introduce a novel elastocapillary phenomenon in hairs assembled into ring-shaped cross sections thus forming hairy-tubes composed of an empty hole surrounded by a hairy wall. The heterogeneous hairy tubes have two distinct spacing length scales: the narrow spacing among the individual hairs and the large inner diameter of the tube which is a few millimeters. The hairy tubes are immersed in a liquid bath, and once they pierce the liquid interface, the fibers self-assemble due to the capillary action. In particular, we observe that the drainage dynamics between the fibers play an important role in the deformation trend, which has two distinct modes. The fibers locally coalesce in the low drainage rate forming tubes having smaller inner and outer diameters than the dry counterparts with denser fiber packing within the walls, while they completely collapse into round bundles and eliminate the internal diameter at the high drainage rate. Based on the physics of elastocapillarity, we theoretically and experimentally explain the shape shifting induced by surface tension, depending on the structure size and the drainage speed. This study provides the model system of capillary induced self-assembly of heterogeneous hairy structures, which have far more applications, such as micro/nanoscale manufacturing and soft actuators.

3:52PM A36.00005 Electric field driven aggregation of negatively and positively polarized particles in dilute suspensions1. BORIS KHUSID, QIAN LEI, EZINWA ELELE, New Jersey Institute of Technology — We will present data on the electric field driven particle aggregation in dilute suspensions of nearly neutrally-buoyant negatively and positively polarized particles. Following the application of a sufficiently strong high-frequency AC field to both suspensions, particles aggregated head-to-tail into chains that bridged the gap between two electrodes. Once a weak DC field was added, negatively polarized particles formed a cellular pattern, in which large-scale particle-free domains were enclosed by particle-rich thin walls. The appearance of such patterns in suspensions of negatively polarized particles in a strong AC field was observed by Kumar, Khusid, Acrivos, PRL95, 2005 and Agarwal, Yetihra, PRL102, 2009. However, formation of cellular structures is not predicted by current theories for the field induced particle aggregation in polarized suspensions.

4:05PM A36.00006 Fabrication of water-in-water colloidosomes from aqueous two-phase systems using droplet microfluidics. WEI GUO, YAGE ZHANG, SHIPEI ZHU, ANDERSON H. C. SHUM, Department of Mechanical Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong — We describe the fabrication of stable and monodispersed colloidosomes derived from water-in-water microdroplets using an integrated high-throughput microfluidic system. Liquid-liquid phase separation of aqueous two-phase systems (ATPS) inside the microdroplets is used as the driving force to form the semipermeable shell of colloidosomes. Droplets of water-in-oil are firstly generated in a microfluidic flow-focusing device, where aqueous dextran solutions with the addition of negative-charged nanoparticles are used as dispersed phase. Then we use a pico-injector to introduce another component, aqueous polyethylene glycol (PEG) solutions with the addition of positive-charged polyelectrolytes, into the microdroplets. Phase separation inside the pico-injected droplets happens due to the non-equilibrium osmotic pressure between the two components, triggering the formation of crosslinked shells by complex coacervation. Our confocal images and stiffness test show that these shells have stable morphology and robust structures. Finally, we use a microfluidic sorting module to transfer those droplets containing crosslinked shells from oil phase to aqueous PEG phase, allowing the fabrication of water-in-water colloidosomes in a high-throughput way.
interphase coupling. We are able to estimate subgrid force fluctuations reasonably well, and thereby greatly enhance the fidelity of mesoscale simulations through improved modeling.

70% of the observed force variation. Since precise location of each particle is known in an Eulerian-Lagrangian simulation, our model would be able to correlate the microscale variation of the drag and lift force with the local anisotropy of each particle’s neighborhood. Given the distribution maps extracted from direct numerical simulations, our model takes advantage of the statistical information of the arrangement of neighbors to predict the macroscopic net particle deposition profile. Our work thus demonstrates how pore-scale transport dynamics of colloidal particles in a model 3D porous medium using confocal microscopy. For the first time, we characterize the interplay between particle deposition and flow in a complex 3D porous medium. However, this behavior is difficult to model due to diverse processes that may arise, including capillary forces and fluid flow.

Our research was executed through the NETL Research and Innovation Centers Advanced Reaction Systems FWP. Research performed by Leidos Research Support Team staff was conducted under the RSS contract 89243318CFE000003.

**3:39PM A37.00004 Colloidal Particle Flow through Porous Media: A Multiscale Study**

NAVIN BIZMARK, Princeton Institute for the Science and Technology of Materials, Princeton University

RODNEY PRIESTLEY, SUJIT DATTA, Department of Chemical and Biological Engineering, Princeton University

RODNEY PRIESTLEY, SUJIT DATTA, Department of Chemical and Biological Engineering, Princeton University — Colloidal particles hold promise for improved oil recovery and groundwater aquifer remediation. These applications rely on the transport of injected particles through a subsurface three-dimensional (3D) porous medium. However, this behavior is difficult to model due to diverse processes that may arise, including particle advection through the pore space by fluid flow, adsorption and deposition onto the solid matrix, and erosion or resuspension. Moreover, these processes are particularly difficult to study experimentally due to the opacity of typical 3D media. Here, we directly visualize the transport of colloidal particles in a model 3D porous medium using confocal microscopy. For the first time, we characterize the interplay between particle adsorption and erosion at the pore scale. Analysis of these pore-scale processes allows us to determine the net particle deposition rate, which enables us to predict the macroscopic net particle deposition profile. Our work thus demonstrates how pore-scale transport dynamics of colloidal particles can be controlled to achieve desired macroscopic goals with consequences for oil recovery, aquifer remediation, and other emerging applications.

3:00PM A38.00001 Controlling capillary fingering using pore size gradients in dis-

ordered media, NANCY LU, CHRISTOPHER BROWNE, DANIEL AMCHIN, Department of Chemical and Biological Engineering, Princeton University, JANINE NUNES, Department of Mechanical and Aerospace Engineering, Princeton University, SUJIT DATTA, Depart-

dment of Chemical and Biological Engineering, Princeton University — Capillary fingering is a displacement process that can occur when a

non-wetting fluid displaces a wetting fluid from a homogeneous disordered porous medium. Here, we investigate how this process is influenced

by a pore size gradient. Using microfluidic experiments and computational pore-network models, we show that the non-wetting fluid displacement

behavior depends sensitively on the direction and the magnitude of the gradient. The fluid displacement depends on the competition between a

pore size gradient and pore-scale disorder; indeed, a sufficiently large gradient can completely suppress capillary fingering. By analyzing capillary

forces at the pore scale, we identify a non-dimensional parameter that describes the physics underlying these diverse flow behaviors. Our results

thus expand the understanding of flow in complex porous media and suggest a new way to control flow behavior via the introduction of pore

size gradients.

3:13PM A38.00002 Evolution of a liquid-liquid interface through a symmetric pore

doublet model.1, JONATHAN SILES GARNER, ANCHAL SAREEN, ELLEN LONGMIRE, University of Minnesota — In applications

such as oil recovery, diagnostics and printing, the displacement of one liquid from a porous medium is often achieved by injecting another liquid.

In these situations, it is typically desired to minimize entrapment of the receding fluid in the pores. In this study, we investigate experimentally

the liquid entrapment process as the liquid-liquid interface evolves through a quasi-two-dimensional pore doublet model. Experiments are

performed for various Weber numbers (We) of the invading liquid for three flow geometries. The entrapped volume was found to increase

significantly with increasing Weber number of the invading fluid. Beyond a ‘critical’ We, when the inertia of the invading non-wetting liquid

is high compared to the surface tension of the interface, the non-wetting liquid pieces through the pockets of the entrapped receding liquid

leading to ‘instability’. It was also found that the entrapped volume can be reduced significantly by making the trailing edge of posts pointed.

This geometry also delays the interface ‘instability’ to higher We. Effects of the fluid viscosity ratio and We number of the invading fluid will

be discussed in detail for three post geometries.

3:26PM A38.00003 Numerical Simulation of Immiscible Pore Scale Flow: Wettability and Dynamics, SOHEIL ESMAEILZADEH, ZHIPENG QIN, Stanford University, AMIR RIAZ, University of Maryland, HAMDI TCHLEPI, Stanford University — Accurate characterization of fluid-fluid interfacial dynamics is crucial for modeling pore-scale multiphase flows common in water resources management and subsurface applications. In this work, we propose a framework to accurately capture the dynamics of the capillary dominated pore-scale fluid-fluid interfaces in the presence of complex-shaped confinements. The incompressible Navier-Stokes equations are coupled with a multiscale sharp-interface level-set method and a direct-forcing based immersed boundary approach on a cartesian mesh to capture the interfacial dynamics. With the viscous terms being treated semi-implicitly, and a dynamic contact-line model suited for curved surfaces, we study the effects of wettability, contact angles, and pinch-off dynamics.

Keywords: water resources management, pore-scale, level-set method, immersed boundary, multiphase flow

3:39PM A38.00004 Anisotropic wicking, SOHYUN JUNG, Seoul National University, WONJUNG KIM, Sogang University, HO-YOUNG KIM, Seoul National University — Capillarity-driven wicking of liquids into porous substrates follows Washburn’s rule, in general. Here we show that the wicking dynamics are substantially altered when the substrates are structurally anisotropic or soluble in the liquids. First, when the polymer fibers are aligned in one direction, the non-reactive liquid wicks fast along the direction of the fibers following Washburn’s rule while the wicking still occurs across the fibers exhibiting a power law different from Washburn’s rule. Second, when the polymer is soluble in the liquid, the wicking occurs dominantly across the fibers rather than along them, contrary to our intuition. We show that the rate of soluble wicking is determined by viscosity but independent of surface tension of the solution.

3:52PM A38.00005 Wicking-mediated drying in porous media1, MARTA GONALVES, YESEUL KIM, SKKU Advanced Institute of Nanotechnology, Sungkyunkwan University, JIN YOUNG KIM, Research Center for Advanced Materials Technology, Sungkyunkwan University, NAJAF RUBAB, SKKU Advanced Institute of Nanotechnology, Sungkyunkwan University, TAKESHI ASAI, SUNGCHAN HONG, Institute of Health and Sports Science, University of Tsukuba, BYUNG MOOK WEON, School of Advanced Materials Science and Engineering, SKKU Advanced Institute of Nanotechnology, Sungkyunkwan University — When a water droplet is placed on a porous substrate, wicking and drying come up simultaneously. Wicking is a spontaneous liquid flow through porous media by capillarity and drying is a spontaneous vapor flow by vapor diffusion. Despite simultaneity of wicking and drying in porous media, how wicking affects drying is not clear yet. Here we study how wicking dynamics evolves with time and cooperates with drying dynamics by microscopic observations of water droplets on porous materials such as fabrics and papers. We find that wicking at early stages expands the surface area of absorbed water through porous materials, accelerating the evaporation rates. X-ray microscopy is a powerful tool to observe pore networks and water flows inside wicking fabrics. This result is useful to comprehend cooperation and to improve optimization between wicking and drying in porous media.

4:05PM A38.00006 Transpiration through hydrogels1, MERLIN ARAGON ETZOLD, M. GRAE WORSTER, PAUL F. LINDEN, DAMTP, University of Cambridge — We present experiments and theory relating to transpiration through hydrogel beads in contact with a water reservoir below and evaporating into air above. Experimentally, we find that saturated hydrogel beads shrink until a steady state is reached in which water flows continuously through the beads. The size of the beads in steady state is very sensitive to the evaporation rate, which depends on the relative humidity and speed of the air, and is measurably sensitive to the pressure in the fluid reservoir. Specifically, the beads are smaller when the evaporation rate is larger or the reservoir pressure lower. Our conceptual 1D model proposes that transport in the hydrogel is driven by gradients in osmotic pressure, therefore by gradients in polymer concentration in the hydrogel, which correspond to gradients in swelling. If the evaporation rate or the bottom pressure changes, the adjustment of this gradient requires the bead to change shape. Smaller beads have larger gradients of osmotic pressure, which drive higher transpiration rates and can draw water against larger hydraulic heads.

4:18PM A38.00007 Carbonized sucrose-coated PDMS sponge for highly efficient and self-cleaning solar evaporator, JAEHYEON LEE, SANG JOON LEE, Pohang Institute of Science and Technology — Solar steam generation is a promising technology for seawater desalination and water purification. However, most state-of-the-art technologies are expensive and suffer from insufficient solar-to-evaporation conversion efficiency and fouling problems, which limit their practical applications. Here, we propose a new superhydrophilic thermally-insulated macroporous membrane (STIMM) composed of carbonized sucrose and polydimethylsiloxane (PDMS) as an efficient solar evaporator. The coupled effect of superhydrophilicity and heat localization of STIMM was found to maximize the solar-to-evaporation conversion efficiency. The highest evaporation rate of 7.702 kg/m^2h, 8.7 times higher than that of only water, was achieved with solar-to-evaporation conversion efficiency of 99.8%. The STIMM was applied to obtain pure drinkable water from saline water with 20 wt% salinity, with a 99.907% desalination efficiency. In addition, the macro-pore size of STIMM enabled self-cleaning with 93.1% of salt rejection rate, which mitigates the fouling problem substantially. The present results demonstrate a highly effective and sustainable solar steam generator, which would be applied for solar thermal desalination and water purification systems.

Saturday, November 23, 2019 4:40PM - 5:45PM — Session B01 Free-Surface Flows: Interaction with Physical Structures II 2A - Alfonso Ganan-Calvo, Universidad de Sevilla, ETSI

4:40PM B01.00001 Statistics of extreme body motions in nonlinear wave fields, XIANLIANG GONG, YULIN PAN, Department of Naval Architecture and Marine Engineering, University of Michigan — We consider the statistics of extreme body motions in a nonlinear irregular wave field. In addition to the excitation by extreme waves, the extreme motions can be physically resulted from wave-body resonance or parametric excitation. Therefore, their statistics cannot be directly derived from extreme wave statistics which has been studied extensively. The computation of the statistics, however, requires the Monte-Carlo method, which can become computationally intractable (when coupled with high-fidelity simulations) due to the rareness of the extreme events. In this work, we develop a general framework, which enables an efficient resolution of the statistics of extreme body motions in a nonlinear wave field. This leverages a range of physics and learning based approaches, including nonlinear wave simulations, body response simulations, dimension-reduction techniques, sequential sampling and Gaussian process regression (Kriging). The developed method is benchmarked for its effectiveness in accurately resolving the statistics, and applied to study the extreme statistics of ship roll motions in an evolving narrow-banded nonlinear wave field.
4:53PM B01.00002 Experimental study of improving power conversion capability of a floating point absorber with reactive control technique.\textsuperscript{1} YE LI, QIANLONG XU, ZHILIANG LIN, XIAOBO ZHENG, NAOCE. Shanghai Jiao Tong University, BOYIN DING, BENJAMIN CAZZOLATO, ME, University of Adelaide — One of the biggest challenges for wave energy conversion (WEC) system to be competitive in the renewable market is to maintain a high and stable efficiency from stochastic ocean waves with wide spectrum. To solve this issue, there is an emerging need to develop a reactive control system (RCS) for WEC according to incoming wave condition via feedback control. An advanced boundary element method with viscous correction was developed to analyze the system dynamics. Scaled model tests were conducted in the newly developed multiple function towing tank at SJTU to study the power generation of a floating point absorber with RCS. Incoming wave information is well integrated into control loop with a group of gauges. The results show that power output of RCS can be about 2-3 times higher than that of passive control system (PCS). High efficiency spectrum of RC-WEC ranges 1.5 times wider than PC-WEC’s. Viscous effect increases with power generation coefficient, indicating the significance of geometry optimization with control system optimization together. Power output efficiency decreases as wave height increases, indicating that increasing nonlinear hydrodynamics can degrade the performance of linear control.

5:06PM B01.00003 Wave attenuation by flexible vegetation. CLINT WONG, University of Oxford, PHILIPPE TRINH, University of Bath, JON CHAPMAN, University of Oxford — The study of fluid flows interacting with vegetative structures in coastal regions presents a significant challenge on account of its multi-scale nature. In this talk, we show how compact asymptotic reductions allow us to study surface waves over submerged vegetative regions. The vegetation is modeled as a collection of elastic cantilever beams in cross-flow and is coupled to fluid momentum equations. Our simplified framework provides some advantages to existing models. For example, for rigid plants over a horizontal bed, previous work on linear waves predicts a quadratic decay in wave amplitude. However, by accounting for plant flexibility, we predict a sub-quadratic decay that agrees more closely with experimental observations. Consideration of a varying depth further demonstrates competition between shoaling and vegetative dissipation.

5:19PM B01.00004 The scaling laws of an exploding liquid cylinder irradiated by an ultrashort X-ray pulse\textsuperscript{1} ALFONSO GANAN-CALVO, Universidad de Sevilla, ETSI, 41092 Sevilla, Spain — A general formulation of the partial destruction of a liquid object in vacuum after the sudden deposition of a very large amount of energy is proposed. That energy instantaneously raises the pressure of a portion of the liquid to extreme values and changes its state, which causes its explosive expansion into vacuum and against the rest of the liquid object. When the deformable object is a liquid capillary cylinder or column, the model reduces to a universal equation for the evolution of the expanding gap between the two sides of the exploding liquid column. The theoretical analysis contemplates two asymptotic stages for small and large times from the initiation of the blast, whose asymptotic solutions are fitted to available experimental data. An universal approximate analytical solution is obtained. A complete dimensional analysis of the problem and an optimal collapse of experimental data reveal that the proposed solution is in remarkable agreement with experiments of a jet exploding after being irradiated by an ultrashort and intense X-ray pulse from a X-ray free electron laser (XFEL).

5:32PM B01.00005 The Dynamics of Liquid Sorbents in Open Capillary Channels\textsuperscript{1} SAMUEL MOHLER, MARK WEISLOGEL, Portland State University, NASA COLLABORATION — Direct contact liquid-gas sorbent beds offer unique benefits for spacecraft air quality control. In a recent ISS technology demonstration experiment (CSELS—Capillary Sorbent), two 16-parallel open capillary channel contactors plumbed in series demonstrated passive ‘thin film’ control, modeling both absorption and desorption functions for a potential low-gravity gas scrubbing system for spacecraft. The open wedge-shaped channels mimic terrestrial falling film reactors by exploiting capillary pressure gradients instead of gravity. In this presentation we highlight the fluid mechanics of the process with and without the effects of CO\textsubscript{2} absorption across the surface. We identify the limits of operation, stability, and transients for systems as functions of wedge geometry and working fluid thermo-physical properties. Rare analytical solutions are found that may be applied to enormous systems of n-parallel channels. The analytical approach serves as the building block for massively parallel systems requiring large surface areas to achieve the desired performance.

Session B02 Waves: Surface Waves II

4:40PM B02.00001 Modulation instability and rogue waves for shear flows with a free surface. QING PAN, The University of Hong Kong, ROGER GRIMSHAW, University College London, KWOK WING CHOW, The University of Hong Kong — The evolution of weakly nonlinear, narrow-band wave packets for free surface flows is governed by the nonlinear Schrödinger equation. Rogue waves, unexpectedly large localizations from equilibrium background can occur if the water depth is sufficiently large. In practice, shear currents nearly always occur in oceans, but modeling studies on wave dynamics are usually restricted to the case of linear current. The dynamics of rogue waves in the presence of a linear shear current has been studied in the literature. Generally rogue waves become narrower and with a short period of existence in terms of time if the background plane wave moves against the current. However, the modulation instability can be enhanced when background plane wave moves with the current. Here the investigation is extended to the case of a current with arbitrary vorticity gradient, by enhancing theoretical formulation established earlier by our group. The transient growth rate and the spatial extent of the rogue waves will be reported for two broad classes of velocity profiles, those convex to the right and those convex to the left. And thus knowledge on such focusing mechanisms of free surface waves will be of importance in both nonlinear science and physical oceanography.

4:53PM B02.00002 A new deep water equation for unidirectional surface gravity waves in two dimensions. NAIL S. USSEMBAYEV, KAUST — Using Hamiltonian theory of weakly nonlinear surface waves we derive a set of nonlinear evolution equations describing propagation of unidirectional gravity waves on the surface of a two-dimensional ideal fluid of infinite depth. The proposed equations admit an exact solution in terms of Lambert’s W-function. We compare this solution with the approximate irrotational solution due to Stokes (1847) and the exact rotational solution found by Gerstner (1802). Being irrotational and exact, our solution exhibits a distinctive advantage over the aforementioned classical examples of deep-water gravity waves.
to understand the pair wave creation. Hawking radiation and surface wave-current interactions. Conserved wave activities like pseudomentum and pseudoenergy have been utilized analogous to the celebrated Hawking radiation in Black holes (S.W. Hawking, Nature 1974). Theoretical and numerical investigations on total waves: one oscillating with a positive frequency and the other with a negative frequency. Such a situation is known as the "pair-wave creation", presence of a mean current flowing over a bottom topography have analogies with the Black hole horizon. Refraction of surface waves at the of Dundee, Nethergate, Dundee DD1 4HN, UK, EYAL HEIFETZ, Tel-Aviv University, Tel Aviv 69978, Israel — Surface gravity waves in the for detecting the analogue Hawking effect in a hydraulics laboratory with the aim to support future experimental studies.

The phase velocity pointing in opposite directions. Here we present the correspondence between the Saint-Venant equations for shallow water flows pair had a group velocity and phase velocity both pointing downstream, whereas the second had the unusual property of a group velocity and phase velocity pointing in opposite directions. Here we present the correspondence between the Saint-Venant equations for shallow water flows and furthermore, (ii) the flow speed exceeds the wave speed. At the horizon, the incident shallow water wave splits into two distinct deep water waves: one oscillating with a positive frequency and the other with a negative frequency. Such a situation is known as the "pair-wave creation", analogous to the celebrated Hawking radiation in Black holes (S.W. Hawking, Nature 1974). Theoretical and numerical investigations on total internal reflection and tunneling have been performed using an in-house Higher-order spectral code in order to find deeper analogies between Hawking radiation and surface wave-current interactions. Conserved wave activities like pseudomentum and pseudoenergy have been utilized to understand the pair wave creation.

The effect of wind on wave shape: Shallow water, THOMAS ZDYRSKI, FALK FEDDERSEN, Univ of California - San Diego — Wave shape (e.g., wave skewness and asymmetry) impacts sediment transport, beach morphology, and ship safety. Previous work by the authors showed that wind (via changes in surface pressure) affects wave shape in intermediate and deep water. This effect was most pronounced as the depth (kh) decreased. Here, this work investigates the interaction of wind and wave shape in shallow water. A multiple-scales analysis is applied to waves propagating over a shallow (kh ≪ 1), flat bottom with a variety of wind-induced surface-pressure profiles, such as Jeffreys-type and generalized Miles-type. The shallow depth enhances the influence of wind on wave shape and intensifies the waves’ second-harmonic modes. The results are compared to previous wave-tank experimental data and numerical simulation results.

Wave drag on asymmetric bodies, GRAHAM BENHAM, JEAN-PHILIPPE BOUCHER, ROMAIN LABB, MICHAEL BENZAQUEN, CHRISTOPHE CLANET, LaDHyX, Ecole Polytechnique — More than a century ago, Michell derived an integral formula for the wave resistance on a body, using the approximation of a slender body in an irrotational, inviscid fluid (Michell 1898). The major shortcoming of this formula is that, due to the reversibility of the steady potential flow formulation, it does not distinguish the difference in wave drag when an object with front-back asymmetry moves forwards or backwards. However, it is well known that an asymmetric body with a sharp leading edge and a rounded trailing edge produces a smaller wave disturbance moving forwards than backwards, and this is reflected in the wave drag coefficient. In this talk, we discuss recent experimental observations investigating the effects of body asymmetry on wave drag, and show that these effects can be replicated by modifying Michell’s theory to include the growth of a symmetry-breaking boundary layer. We demonstrate that asymmetry can have either a positive or a negative effect on drag, depending on the depth of motion and the Froude number. We discuss the implications and scope of this work in the context of sports physics, including the design of rowing, kayak and canoe boats.

Jetting in large amplitude axisymmetric capillary gravity waves, RATUL DASGUPTA, SAWSATA BASAK, PALAS KUMAR FARSOIYA, Indian Institute of Technology Bombay — The phenomenon of jetting and accompanying droplet ejection is known to occur in many fluid dynamical situations involving collapse of a gaseous cavity at a liquid-gas interface. In a recent study of free, capillary-gravity oscillations on a quiescent cylindrical pool of liquid [Farsoiya et al J. Fluid Mech., 857, pp. 80-110 (2017)], it has been shown using DNS that jetting may be obtained with an initial interfacial perturbation in the form of a single Bessel mode. Sufficiently large values of wave steepness lead to the formation of a jet at the axis of symmetry that can eject droplets from its tip. In this study, we formulate the solution to the weakly nonlinear, inviscid-irrotational, initial-value problem in axisymmetric cylindrical coordinates using wave steepness as a small parameter and obtain a third order solution for the free surface profile. It is seen that the weakly nonlinear solution is able to describe the onset of jet formation. A detailed discussion of capillary effects along with comparisons with Direct Numerical Simulations, will be presented.

Jetting in large amplitude axisymmetric capillary gravity waves, RATUL DASGUPTA, SAWSATA BASAK, PALAS KUMAR FARSOIYA, Indian Institute of Technology Bombay — The phenomenon of jetting and accompanying droplet ejection is known to occur in many fluid dynamical situations involving collapse of a gaseous cavity at a liquid-gas interface. Fluid Mech., 857, pp. 80-110 (2017)], it has been shown using DNS that jetting may be obtained with an initial interfacial perturbation in the form of a single Bessel mode. Sufficiently large values of wave steepness lead to the formation of a jet at the axis of symmetry that can eject droplets from its tip. In this study, we formulate the solution to the weakly nonlinear, inviscid-irrotational, initial-value problem in axisymmetric cylindrical coordinates using wave steepness as a small parameter and obtain a third order solution for the free surface profile. It is seen that the weakly nonlinear solution is able to describe the onset of jet formation. A detailed discussion of capillary effects along with comparisons with Direct Numerical Simulations, will be presented.

Optimization of a highway infrastructure design through a combined computational fluid dynamics and evolutionary algorithm framework, PENG ZHANG, ANH-VU VO, DEBRA LAEFER, Tandon School of Engineering, New York University, MAURIZIO PORFIRI, Department of Mechanical and Aerospace Engineering and Department of Biomedical Engineering, Tandon School of Engineering, New York University — Design of highway infrastructure significantly influences the performance and fuel consumption of vehicles. However, standard design practice heavily relies on empirical knowledge, based on difficult-to-generalize and cost-prohibitive experiments. Here, we propose a global optimization framework based on computational fluid dynamics (CFD) and evolutionary algorithms to identify the optimal design of a highway infrastructure that minimizes aerodynamic drag on moving vehicles. Although the framework is broadly-applicable, we investigate the design using an actual section of highway with vertical side walls. The highway’s geometry was captured by terrestrial laser scanning and is used to generate the computational domain for three-dimensional CFD. The drag on the vehicles is estimated through CFD using a k-ε turbulence model. Reduction in the aerodynamic drag is attained by enhancing the interaction between the vehicles and the vertical side walls through the addition of solid slabs to the walls. The optimization process is performed through an evolutionary algorithm, which iteratively evolves the size and positioning of the added slabs toward an optimal design. Our results demonstrate that the proposed computational framework can inform future highway infrastructure designs.

4:53PM B03.00002 Unsteady Aerodynamics of Roll-Tacking and Roll-Gybing in an Olympic Class Sailboat, SARAH MORRIS, C. H. K. WILLIAMSON, Cornell University — In this research, we study unsteady sail motion techniques used by Olympic sailors to increase sailboat propulsion. One such technique is for sailors to use bodyweight movements to roll the boat about its longitudinal axis. This motion is used especially for turning the boat in light winds, by either “roll-tacking” (upwind sailing) or “roll-gybing” (downwind sailing). When roll-tacking and roll-gybing, sailors dynamically roll the boat to increase their speed and propel their boats faster than using wind alone; this is in contrast to flat-tacking and flat-gybing, wherein the sailor keeps the boat level (and mast vertical) while turning. Each of these motions is characterized in on-the-water experiments using a Laser sailboat equipped with a GPS, IMU, wind sensor and GoPro camera array. Bringing these motions into the laboratory, we study the underlying vortex dynamics that are responsible for generating extra propulsion in roll-tacking and roll-gybing.

5:06PM B03.00003 Effect of Hybrid-Heave Motions on the Lift of Oscillating Airfoils1, JAY YOUNG, SARAH MORRIS, C. H. K. WILLIAMSON, Cornell University — Inspiration for a number of unsteady airfoil dynamics studies has been drawn from animal locomotion. In the present research, we instead employ a sports-mimetic approach, studying unsteady airfoil motions inspired by sail dynamics. One such technique is “sail flicking,” whereby sailors use their bodyweight motion to roll the boat about its longitudinal axis, flicking the sail periodically. Because sailors do not sail directly into the wind, the boat travels at an angle relative to the apparent wind it experiences. A “flicking” sail will therefore oscillate at non-perpendicular angles to the incoming flow, in a motion we call “hybrid-heave.” We study these hybrid-heave motions with a NACA 0012 airfoil. We find both a “high-lift” and “low-lift” mode. The high-lift mode delivers significant lift increase compared to that of a static airfoil. We study the case of the two distinct modes in terms of instantaneous angle of attack, speed, and vortex dynamics.

5:19PM B03.00004 Effect of Spherical Depressions on Hatchback Cars: A CFD Study, SOURAJIT BHATTACHARJEE, VISHESH KASHYAP, PRIYANSHU MITTAL, B.B. ARORA, Delhi Technological University — A major reason for the development of form drag is vortices generated due to flow separation. This greatly affects the aerodynamics of light vehicles such as hatchback cars. Flow separation may be delayed by the creation of spherical depressions at various locations on the vehicle body, which could lead to a decrease in the form drag. Through a series of studies, the effect of spherical depressions of aspect ratios 2, 4, 6 and 8 was studied separately on the bonnet, doors and roof of a generic hatchback car. 3-D CFD analyses were performed using ANSYS Fluent using a validated computational model. The trends for drag force and drag coefficient with aspect ratio were observed to vary with change in the location of the depressions. While an aspect ratio of 4 delivered the greatest decrease in drag for the bonnet, an increasing trend was observed for the other 2 locations. At higher aspect ratios, the drag was observed to be higher than for the car without depressions. The studies demonstrated the effect of spherical depressions on hatchback cars and elaborated on the importance of location as well as aspect ratio as factors to be considered for low aerodynamic drag.

5:26PM B03.00005 Aerodynamic Assessment of Cross-Wind Airwake Characteristics at Ship Helodeck: A Simplified Approach, SHRISH SHUKLA1, S. N. SINGH2, S. S. SINHA3, Indian Institute of Technology Delhi, R. VIJAYAKUMAR, Indian Institute of Technology Madras — The combined ship-helicopter operation nearby small naval vessels has historically been one of the most challenging tasks. The complexity of this task primarily depends on the ship superstructure, helicopter aerodynamics, and cross-wind conditions. An early assessment of the overall airwake characteristics is one of the challenging tasks. The First-Of-Class Flying Trials are one of the most common methods to assess the resultant airwake characteristics over helodeck. These trials are conducted post-construction of the ship and mainly based on qualitative ratings of the pilot. Also, a wide range of wind conditions cannot be covered, and the scope of further design modification is limited. Thus, there is a strong need to assess the impact of cross-wind conditions on the ship helodeck at the initial design stages. We present an early-stage simplified approach to estimate the aerodynamic impact of cross-winds over ship helodeck with reasonable accuracy. A Reynolds-averaged-Navier-Stokes based parametric analysis has been conducted for six cross-wind conditions to understand the cross-wind phenomena over a simplified frigate ship helodeck. The paper reports the cross-wind airwake assessment based on the criteria set developed by mean velocity gradients and turbulence intensity.

5:45PM B03.00006 Busemann-Sears-Haack hybrid geometries applied toward supersonic vehicles for improved wave drag performance, ANDREW SKLAR, ZVI RUSAK, Rensselaer Polytechnic Institute — We present a new configuration for supersonic aircraft fuselages. It is first demonstrated that the commercial Fluent code provides mesh converged, valid results for inviscid supersonic flows around various configurations compared to classical predictions. Then, by adapting a hybrid geometry of the Busemann bpline shape to a span-wise split Sears-Haack body in the region between the bodies, we present a physically feasible two-body configuration that reduces shock wave interference between the two bodies and lowers the wave drag per volume of a given fuselage volume and length. The reduction is about 50% when compared to the Sears-Haack body with same volume and length. In addition, when applied to non-enclosed geometries, the Busemann bpline experiences none of the wave drag spikes and hysteresis that were found with bpline configurations. Preliminary studies into effects of viscosity for supersonic flows at high Reynolds numbers show that the total drag is limited to 25% greater than inviscid flow results. This effect has also been extended to a triple body configuration, which further cuts the drag per volume to less than 40% of the equivalent Sears-Haack body.

5:58PM B03.00007 String Stability in Energy-Saving Formation Flight1, PHILIPPE CHATELAIN, JAMES RIEHL, ESTEBAN HUFSTEDLER, JULIEN HENDRICKX, Université Catholique de Louvain — Formation flight of fixed-wing aircraft provides the opportunity to save substantial energy by exploiting the upwash created by vortical wakes. For the most efficient flight, the aircraft need to carefully track the relative wake position of their leader, which may move due to turbulence or maneuvering of the leader. The tracking errors may grow as the disturbances propagate to aircraft further downstream, resulting in ‘string instability’. This is more commonly examined in automobile platoons, and has not been adequately examined with respect to efficient aircraft formations. We discuss some pitfalls and trade-offs involved in designing string stable controllers for this system, and describe a controller that achieves both string stability and energy efficiency.

1This project has received funding from the European Research Council under the European Unions Horizon 2020 research and innovation program, grant agreement No 725627.
compared with the experiments. The secondary flow effect in the transport equation. The numerical results of depth-averaged particle concentration profile are presented and the effect of the particle accumulation, we extract the particle flux as a function of local particle concentration from the experiments and include system mathematically by considering the depth-averaged particle transport equation and suspension balance model. To capture the physical lead to the gradual accumulation of particles on the advancing oil-air interface. This particle accumulation results in the fingering of an otherwise stable fluid-fluid interface. While the previous works by Xu and colleagues have focused on the resultant instability, one unexplored lead to inertia, is key to triggering hysteresis. To understand this link between friction and hysteresis, we measured the suspension rheology close even without inertia. By using microscale particles whose interparticle friction can be turned off, we show that microscopic friction, conversely to the flow onset for frictional and frictionless suspensions. We show that the flow rule for frictionless particles is monotonous with a power law of exponent 0.05 ± 0.05, in close agreement with the previous theoretical prediction, 0.35. By contrast, the flow rule for frictional particles suggests a velocity-weakening behavior. These findings show that hysteresis can occur in particulate media without inertia, and by highlighting the role of microscopic friction, it questions the intimate nature of this phenomenon.

4:53PM B04.00002 Self-similarity in particle accumulation at fluid-fluid interface. LI WANG, YUN CHEN, RUI LUO, SUNGYON LEE, University of Minnesota — When the mixture of viscous oil and non-colloidal particles displace air between two parallel plates, the coupled effects of shear-induced migration of particles and the secondary flow near the interface lead to the gradual accumulation of particles on the air-oil interface. This particle accumulation results in the fingering of an otherwise stable fluid-fluid interface. While the previous works by Xu and colleagues have focused on the resultant instability, one unexplored yet striking feature of the experiments is the self-similarity in the concentration profile of the accumulating particles. In this talk, we model the system mathematically by considering the depth-averaged particle transport equation and suspension balance model. To capture the physical effect of the particle accumulation, we extract the particle flux as a function of local particle concentration from the experiments and include the secondary flow effect in the transport equation. The numerical results of depth-averaged particle concentration profile are presented and compared with the experiments.

5:06PM B04.00003 Surface instability of shear-thickening suspensions down an inclined plane. BAPTISTE DARBOIS TEXIER, BLOEN METZGER, HENRI LHUISSIER, YOEL FORTERRE, Aix-Marseille University, IUSTI-CNRS UMR 7343, 13453 MARSEILLE, FRANCE TEAM — Shear-thickening of dense suspensions is one of the most appealing phenomena of science festivals. The dramatic increase of the viscosity with the shear stress is now understood as a frictional transition occurring above a critical stress set by a repulsive interaction between particles. Here, we investigate the stability of a thin film of cornstarch suspension flowing down an inclined plane. At low packing fractions, the film is unstable above a critical Reynolds number given by the well-known Kapitza criterion for Newtonian fluids. However, at high packing fractions, as shear-thickening becomes discontinuous, a new instability emerges at Reynolds numbers much smaller than the Kapitza threshold. We show that this instability arises from the characteristic S-shape of the rheological law.

5:19PM B04.00004 Particle-induced miscible fingering. RUI LUO, YUN CHEN, SUNGYON LEE, University of Minnesota Twin Cities — We experimentally inject silicone oil into the mixture of oil and non-colloidal particles inside a Hele-Shaw cell, to investigate the connection between miscible fingering and the flow structure that develops in the thin gap. Previous studies with pure fluids have demonstrated that the onset of miscible fingering coincides with the transition from a smooth tongue-like structure to a sharp front between invading and defending fluids inside the thin gap. Our current experiments reveal the same general behavior at the onset of miscible fingering, which we capture qualitatively using a continuum model. However, beyond the onset, we observe distinctly different morphologies of miscible fingering, which depend on the ratio of the gap thickness to particle diameter. We present the new quantitative measurements that highlight these differences and discuss how the wall confinement may alter the particle dynamics and the resultant fingering patterns.

5:32PM B04.00005 Experimental and numerical studies of particle-laden fluid flows over a porous media model. EILEEN HAFFNER, CHANGWOO KANG, University of Illinois at Chicago, NINA SHAPLEY, Rutgers University, The State University of New Jersey, Laboratory, Seattle, University of Illinois at Chicago — Suspension flows have been extensively studied through various experimental techniques and numerical simulations but only in smooth channels. On the other hand, flow of pure Newtonian fluid over porous media has been the topic of several investigations. However, to the best of the author’s knowledge, how these two engineering systems relate to one another is still unknown. This study was conducted to examine the interaction between various suspensions over a porous media model. Two experimental techniques were utilized, particle image velocimetry (PIV) and nuclear magnetic resonance (NMR) imaging. The PIV data provided two dimensional velocity vector fields which was used to extract slip velocity and shear rate at the interface between the free flow region and the porous media for dilute suspension flows. The NMR measurements provided three-dimensional velocity and concentration information through and above the porous media for higher concentrated suspensions. It was found that the slip velocity, shear rate, and concentration profiles are strongly dependent on the suspension concentrations as well as the geometry and properties of the porous media. Theoretical simulations were developed and compared to the experimental results, showing good agreement in the free flow region.}

5:45PM B04.00006 Hysteresis in viscous suspensions. HUGO PERRIN, CECILE CLAVAUD, BLOEN METZGER, CNRS - IUSTI, MATTIEU VYAYART, EPEF, YOEL FORTERRE, CNRS - IUSTI — Hysteresis is a major feature of the solid-liquid transition in granular materials. This property, by allowing metastable states, can potentially yield catastrophic phenomena such as landslides. The origin of hysteresis in granular flows is still debated. However, most mechanisms put forward so far rely on inertia at the particle level. Here, we study the avalanche dynamics of non-Brownian suspensions in slowly rotating drums and reveal large hysteresis of the avalanche angle even without inertia. By using microscale particles whose interparticle friction can be turned off, we show that microscopic friction, conversely to inertia, is key to triggering hysteresis. To understand this link between friction and hysteresis, we measured the suspension rheology close to the flow onset for frictional and frictionless suspensions. We show that the flow rule for frictionless particles is monotonous with a power law of exponent 0.37 ± 0.05, in close agreement with the previous theoretical prediction, 0.35. By contrast, the flow rule for frictional particles suggests a velocity-weakening behavior. These findings show that hysteresis can occur in particulate media without inertia, and by highlighting the role of microscopic friction, it questions the intimate nature of this phenomenon.
**5:58PM B04.00007 Mixing in sheared suspensions**, REGIS TURUBAN, HENRI LHUISSIER, BLOEN METZGER, JUSTI CNRS UMR 7343 Marseille France, GEP TEAM — Mixing occurs spontaneously in sheared suspensions even at low Reynolds number. The presence of particles induces disorder which lead to exponential elongations within the fluid: concentration levels thus quickly spread and decay. We experimentally characterize the evolution of the concentration PDFs of a blob of fluorescent dye initially injected in an index-matched suspension. High precision optical imaging technics reveal for the first time the finest spatial details of the concentration field possibly generated by this chaotic flow (Batchelor scales). We find that at short times, the evolution of the concentration PDFs are correctly predicted by a model based solely on the stretching kinematics. At longer times, we show that to predict the experimental observations, the model should also include the effect of coalescence between adjacent lamellae of dye.

**Saturday, November 23, 2019 4:40PM - 6:11PM — Session B05 Compressible Flows: Shock Waves and Explosions**

**4:40PM B05.00001 Scale-invariant Homentropic Compressible Flows and Their Application to the Noh Problem**, JESSE GIRON, Arizona State University, SCOTT RAMSEY, ROY BATY, Los Alamos National Laboratory — The purpose of this work is to examine the group invariance properties of the inviscid Euler equations, subject to an equation of state (EOS) where the fluid pressure is regarded solely as an arbitrary function of the fluid density. We derive the conditions under which the resulting homentropic Euler equations and associated shock jump conditions are invariant under scaling groups. The invariance properties of these relations are used to construct a Noh-like solution featuring a constant velocity stagnation shock. For this solution to exist, we demonstrate that the EOS must satisfy a transcendental algebraic relation.

1This work was supported by the U.S. Department of Energy (DOE) through the Los Alamos National Laboratory. Los Alamos National Laboratory is operated by Triad National Security, LLC, for the National Nuclear Security Administration of the DOE (contract number 89233218CNA000001).

**4:53PM B05.00002 Quasi-Similar Converging Shock Flows for a Mie-Gruneisen Equation of State**, EMMA SCHMIDT, SCOTT RAMSEY, ROY BATY, Los Alamos National Laboratory — The Guderley hydrodynamic test problem is an example of a self-similar, scale-invariant solution of the inviscid Euler equations. It consists of an infinitely strong shock wave converging to an axis or point of symmetry, where the defined flow has the notable property of being independent of a system of units. A key piece of the self-similar analysis is selecting a material that exhibits scale invariant behavior. The symmetry properties of the Euler equations have been used by several authors to determine the general form of an equation of state (EOS) that permits the existence of scale-invariant solutions. However many widely used EOSs, such as the Mie-Gruneisen EOS for crystalline solids, are not of the required form. We propose a joint similarity-perturbative analysis that modifies the classical self-similar solutions of the Euler equations to represent non-ideal material behavior, and perform the quasi-similar analysis of the Guderley problem in a non-ideal material defined by the Mie-Gruneisen EOS.

**5:06PM B05.00003 Numerical modeling of solid-cluster evolution applied to the nanosecond solidification of water through ramp and shockwave compression**, DANE STERBENTZ, University of California, Davis, PHILIP MYINT, Lawrence Livermore National Laboratory, JEAN-PIERRE DELPLANQUE, University of California, Davis, JONATHAN BELOF, Lawrence Livermore National Laboratory — Classical nucleation theory (CNT) is a promising way to predictively model the sub-microsecond kinetics of rapid phase transitions that occur under ramp or shock compression, such as the suite of experiments performed over the past two decades on the solidification of liquid water to the high-pressure ice VII phase. We model the liquid water–ice VII phase transformation in these hydrodynamic-loading experiments using a numerical discretisation scheme to solve the Zel’dovich–Frenkel partial differential equation (a fundamental CNT-based kinetic equation that describes the statistical time-dependent behavior of solid cluster formation and accounts for transience in the nucleation kinetics) as well as through hydrodynamics simulations. We have also developed a new dimensionless parameter that may be applied a priori to predict whether or not transient nucleation will be important in a given ramp- or shock-compression experiment.

1This work was performed under the auspices of the U.S. Department of Energy (DOE) by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. We thank A. Arsenlis, D.P. McNabb, B. Wallin, and C. Clouse for funding and project support. Program support was also provided by the DOE NNSA Laboratory Residency Graduate Fellowship.

**5:19PM B05.00004 Shock-wave structure according to the Navier–Stokes–Fourier constitutive relations**, FRANCISCO J. URBIE, ROSA M. VELASCO, Universidad Autonoma Metropolitana — The Navier–Stokes–Fourier constitutive equations are used to study plane shock–waves in dilute gases. We use the soft sphere model in which the viscosity and thermal conductivity are proportional to a power of the local temperature: \( \eta, \kappa \sim T^\sigma \), \( \sigma \) being the viscosity index. We show that the experimental normalized density profiles for argon can fit with the viscosity index. Results form the direct simulation Monte Carlo method and with transport coefficients obtained from ab initio potentials are also considered.

**5:32PM B05.00005 Non-classical behavior in shock-compressed gas mixtures**, PATRICK WAYNE, PETER VOROBIEFF, CAROLINA SHAHEEN, DANIEL FREELONG, C. RANDALL TRUMAN, University of New Mexico — Rankine-Hugoniot (R-H) equations, while assuming a calorically perfect gas, provide a good approximation for real gases undergoing shock compression. Our experiments focus on problems that arise when an attempt to predict post-shock gas properties is made for a non-reacting mixture of two gases with highly disparate properties (hydrogen and sulfur hexafluoride). Although the range of Mach numbers we consider is quite modest (1.2 to 2.0), we observe major deviations from the behavior that classical models predict. The latter include R-H equations in combination with either Dalton’s or Amagat’s law to characterize the gas mixture. Moreover, we observe these deviations to persist on time scales much longer than those historically associated with non-equilibrium behavior due to shock front passage.

Maxwell Koger, Conor Pace, Michael Vu, Oleg Goushcha, Manhattan College — A unique propulsion system has been assembled in which a flow is driven using a fan actuated at its outer diameter rim. This fan configuration eliminates the need for a shaft and a centerline hub required by the conventional fan designs allowing for an undisturbed flow through the centerline region. Also, in our design the fan blades extend from the rim inward towards the centerline. Blades at the outer radius are connected to the rim. The inner radius blade tips are located in a relatively low-flow region associated with small tangential velocity of the fan near the centerline. Therefore, the tip vortices and the associated noise produced by the tip vortices should be minimized compared to the conventional propeller configuration where blade tips are located in a high-tangential velocity region associated with the outer radius. We present an experimental study of noise signature from the tandem airfoil configuration. Near-field measurements have been carried out to understand the mechanism leading to the noise reduction by studying how surface pressure fluctuations vary over the serration root and tip planes. The near-field hydrodynamic analysis obtained using turbulence quantities are estimated from the refractive images and show variations as a function of confinement thickness.

5:19PM B06.00004 The Propeller-Induced Cavitation Noise Source: Experimental Measurements and Numerical Solutions. DUNCAN MCINTYRE, MOSTAFA RAHIMPOUR, University of Victoria, GIORGIO TANI, FABIANA MIGLIANTI, MICHELE VIVIANI, University of Genoa, ZUOMIN DONG, PETER OSHKAI, University of Victoria — Propeller-induced cavitation dominates the mid-to high-frequency range of underwater radiated noise emitted by ships, representing a significant threat to marine ecosystems. The development of mitigation strategies for noise pollution requires predictive models, which are challenging to develop due to the varied, multiscale, and multi-physical nature of the phenomenon. One promising technique for predicting the detailed behaviour of the propeller cavitation noise relies on the use of URANS solutions of the cavitating flow with a volume-of-fluid cavitation model as an input for acoustic modelling with a porous surface formulation of the Ffowcs Williams-Hawking analogy. We present an application of this methodology involving the reproduction of model-scale experiments in a cavitation tunnel. We focused on ten loading conditions of a controllable pitch propeller that resulted in four distinct regimes of cavitation. Performance of the hydrodynamic model varied depending on the cavitation regime. Cavities attached to propeller blades well, but regimes involving cavities within shed vortices were not reproduced well. The numerical model was effective in predicting the shapes of acoustic spectra, but the absolute sound levels were overpredicted.

We acknowledge the support of the Clean Transportation Initiative of Transport Canada, the Natural Sciences and Engineering Research Council of Canada, Compute Canada, and our industrial collaborators.

5:32PM B06.00005 Noise Reduction Mechanism of a High-Lift Airfoil’s Leading-Edge Device. RINIE AKKERMANS, PAUL BERNICKE, TU Braunschweig — Airframe noise is a major part of the total noise produced by an aircraft during its landing phase, of which the wing’s leading-edge device (i.e., slot) is a major contributor. In this contribution, the noise reduction of such slat devices is investigated by means of Overset-LES simulations. It solves the compressible Navier-Stokes equations in perturbation form over a background flow, supplemented by a sub-filter-stress model. Two geometries are considered, i.e., a reference and a modified long-cord slat geometry. The effect of the long-cord slat on the turbulent sound sources is investigated by mainly considering turbulence statistics and span-wise coherence length in the slat cove region. Furthermore, acoustic far-field propagation reveals the influence of long-cord slat on the directivity. Results show that the noise reduction is mainly resulting from a shielding effect by the long-cord slat, rather than modification of the turbulent sound source in the slat cove region itself.

5:45PM B06.00006 An experimental analysis on efficacy of perforated plates of varying orifice quantity. T DHANACHANDRAN THANAPAL, JINLIANG HENG, BASMAN ELHADIDI, WAI LEE CHAN, Nanyang Technological University — Combustion engines typically generate significant noise signatures, and the latter constitutes a source of noise pollution. One method of reducing such noise is by disrupting the acoustic waves using acoustic dampers, which in this work is in the form of perforated plates. As air flows through the orifices of the plates, an unsteady jet flow is generated, which will further interact with the acoustic noise and, through viscous dissipations, convert the acoustic fluctuations into non-radiating vortical fluctuations. With the recognition of this fundamental mechanism, the objective of this work is to understand the effectiveness of the perforated plates as acoustic dampers. Fast Fourier transformation was used to analyse the resulting microphone data, showing that the single-orifice plate functioned as an acoustic resonator instead of a damper. In contrast, the multiple-orifice plate functioned as acoustic damper, producing approximately 50% reduction in noise. This finding is consistent with prior investigation where plates with higher open area ratios perform better at reducing acoustic noise. Both single- and multiple-orifice plates were relatively insensitive to the bias flow rate, although the single-orifice plate performance did improve slightly when the bias flow rate was increased.

5:58PM B06.00007 Numerical analysis of the characteristics of Helmholtz resonators with multiple necks. JINLIANG HENG, T DHANACHANDRAN THANAPAL, WAI LEE CHAN, BASMAN ELHADIDI, Nanyang Technological University — Helmholtz resonators are commonly used in combustion engines to reduce engine noise and tackle combustion instability issues. A resonator, typically consisting of a fixed volume cavity and a neck has a resonant frequency that is a function of the speed of sound, neck cross-sectional area, cavity volume, and neck length. For a resonator with multiple necks, the analytical expression is able to determine a single value for its resonant frequency. However, in this work involving a cavity with multiple necks, experiments have shown that multiple frequencies are present. Subsequent numerical simulations utilizing the Lattice Boltzmann method also yield reasonable agreement with experiments, suggesting that the multiple-frequency phenomenon may be attributed to interactions between different necks, and may be specific to the current experimental setup. Further simulations with sinusoidal and pulse acoustic source will be performed for further insights to the flow associated with a resonator with multiple necks, from which the multiple-frequency phenomenon may be explained.

Saturday, November 23, 2019 4:40PM - 5:58PM – Session B07 Suspensions: General IV 211 - Bryan Quaife, Florida State University

Awards for Oscillatory Flow

practical ability for oscillatory flow, compared to steady flow, for the analysis of smaller sample volumes. I will also discuss the impact of the channel depth, width, pressure gradient and frequency of oscillations on the alignment in the system. For the specific application of pathogen detection via binding of M13 bacteriophage, I will explore with the narrow channel flow equations, the latter modified to incorporate mechanical anisotropy induced by the particles. The linear dichroism orientation dynamics of a suspension of slender microscopic fibres. The model couples the Fokker-Planck equation for Brownian suspensions and, more generally, extend to the rheology of mixed suspensions having particles with different rigidities, as well as offering possibilities for volume fraction of rigidified cells. These results are relevant to better characterize SCA, provide useful insights relevant to blood transfusions, and, more generally, extend to the rheology of mixed suspensions having particles with different rigidities, as well as offering possibilities for developments in the field of soft material composites.

ABHILASH REDDY MALIPEDDI, KAILIK SARKAR, The George Washington University — We compute the shear-induced gradient-diffusivity of red blood cells (RBC) from direct numerical simulation using a dynamic structure factor approach. Macro-scale phenomena, such as diffusivities, result from the micro-scale dynamics of RBCs. RBCs in shear flow exhibit extremely rich and complex motion such as tank-treading, tumbling and swinging. They affect the shear-induced diffusivity analyzed here. As the shear rate increases, the diffusivity increases initially due to the increased deformability of the cells, and thereby enhanced interactions between them. On further increase of the shear rate, a transition point is reached where the diffusivity briefly decreases before increasing again. The decrease corresponds to the transition of the single cell dynamics from the tumbling regime to the tank-treading regime. During tumbling of an RBC, due to the larger swept volume of the tumbling shape, its effective size and correspondingly the length scale for diffusion is larger than what is indicated by the cell volume. In the tank-treading regime, this effect is absent in lowered diffusivity.

ABHILASH REDDY MALIPEDDI, KAILIK SARKAR, The George Washington University — We compute the shear-induced gradient-diffusivity of red blood cells (RBC) from direct numerical simulation using a dynamic structure factor approach. Macro-scale phenomena, such as diffusivities, result from the micro-scale dynamics of RBCs. RBCs in shear flow exhibit extremely rich and complex motion such as tank-treading, tumbling and swinging. They affect the shear-induced diffusivity analyzed here. On further increase of the shear rate, a transition point is reached where the diffusivity briefly decreases before increasing again. The decrease corresponds to the transition of the single cell dynamics from the tumbling regime to the tank-treading regime. During tumbling of an RBC, due to the larger swept volume of the tumbling shape, its effective size and correspondingly the length scale for diffusion is larger than what is indicated by the cell volume. In the tank-treading regime, this effect is absent in lowered diffusivity.

YOUNG, New Jersey Institute of Technology, DAVID WOOD, University of Minnesota, JOHN HIGGINS, Massachusetts General Hospital, ZHANGLI FENG, University of Notre Dame, HOWARD STONE, Princeton University — Sickle cell anemia (SCA) is a disease that affects red blood cells (RBCs) within blood. Healthy RBCs are highly deformable objects that under flow can penetrate blood capillaries smaller than their typical size. In SCA there is an impaired deformability of some cells, which are much stiffer and with a different shape than healthy cells, and thereby affect regular blood flow. It is known that blood from patients with SCA has a higher viscosity than normal blood. However, it is unclear how the rigidity of cells is related to the viscosity of blood, in part because SCA patients are often treated with transfusions of variable amounts of normal RBCs and only a fraction of cells will be stiff. Hence, we report systematic viscosity measurements and numerical simulations of a suspension varying the fraction of RBCs affected by increased rigidity within a suspension of healthy cells. Our results show that there is a rheological signature within blood viscosity to clearly identify the fraction of rigidified cells within healthy deformable cells down to a 5% volume fraction of rigidified cells. These results are relevant to better characterize SCA, provide useful insights relevant to blood transfusions, and, more generally, extend to the rheology of mixed suspensions having particles with different rigidities, as well as offering possibilities for developments in the field of soft material composites.

GEMMA CUPPLES, DAVID SMITH, University of Birming-
ham, MATTHEW HICKS, Linear Diagnostics Ltd, ROSEMARY DYSON, University of Birmingham — Flow linear dichroism is a biophysical spectroscopic technique that exploits the shear-induced alignment of elongated particles in suspension. This talk is focussed around the broad aim of optimising the sensitivity of this technique by improving the alignment of these particles, with a specific application of a handheld synthetic biotechnology prototype for waterborne-pathogen detection. I will describe a model of steady and oscillating pressure-driven channel flow and orientation dynamics of a suspension of slender microscopic fibres. The model couples the Fokker-Planck equation for Brownian suspensions with the narrow channel flow equations, the latter modified to incorporate mechanical anisotropy induced by the particles. The linear dichroism signal is estimated through integrating the perpendicular components of the distribution function via an appropriate formula that takes the bi-axial nature of the orientation into account. For the specific application of pathogen detection via binding of M13 bacteriophage, I will explore the impact of the channel depth, width, pressure gradient and frequency of oscillations on the alignment in the system. I will also discuss the practical ability for oscillatory flow, compared to steady flow, for the analysis of smaller sample volumes.

4:40PM B08.00001 Flying in a superfluid: starting flow past an airfoil. SETH MUSSER, Massachusetts Institute of Technology, DAVIDE PROMENT, University of East Anglia, MIGUEL ÓNORATO, University of Turin, WILLIAM IRVINE, University of Chicago — We investigate the development of superfluid flow around an airfoil accelerated to a finite velocity from rest. Using both simulations of the Gross-Pitaevskii equation and analytical calculations we find striking similarities to viscous flows: from the production of starting vortices to the convergence of the airfoil circulation onto a quantized version of the classical Kutta-Joukowski circulation. Using a phenomenological argument we predict the number of vortices nucleated by a given version of the classical Kutta-Joukowski circulation. Finally we analyze the lift and drag acting on the airfoil.

4:53PM B08.00002 Small particle motions in inhomogeneous super fluid turbulence. TAKUMI MARUYAMA, SHINICHIRO WAKI, SOU SUZUKI, VOLKER SONNENSCHEIN, HIDEKI TOMITA, YOSHIYUKI TSUJI, TETSUO IGUCHI, Nagoya University — Lagrangian trajectories of small particles in a fully developed turbulent state are studied in a rectangular duct. A plate heater is attached on the bottom to generate the thermal counter flow. The bath temperature is changed from 1.9 K to 2.1 K, and is controlled within 0.1 mK. Small He* particles of micron size and their trajectories are recorded. Their motions indicate complex features depending not only on bath temperature and heater power, but also on particle size. Particle motions near the wall are different from those at duct center. We report the effect of flow inhomogeneity on the particle motions. Smaller particle tends to be affected by the inhomogeneity than the larger particle sizes. To characterize the particle motions, the Hurst exponent is defined by $|\langle x(t+\tau) - x(t)\rangle| \propto \tau^\beta$, where $x(t)$ denotes the particle position at time $t$. It is found that there is a characteristic time scale $\tau_0$. For small time separation, $\tau \ll \tau_0$, the exponent $\beta$ is small. However, for large time separation, $\tau_0 \ll \tau$, $H$ is nearly $1/2$. [1] W.Kubo and Y.Tsui, Journal of Low Temperature Physics, 2010, Volume 196, pp 170176

5:06PM B08.00003 Quantum turbulence exploration using the Gross-Pitaevskii equation¹, LUMINITA DANAILA, University of Rouen Normandy, MICHIAKUZU KOYAYASHI, Kyoto University, FRANKLY LUDDENS, Corentin LOTHODE, University of Rouen Normandy, PHILIPPE D'ARNAUDEAU, University of Poitiers, IONUT DANAILA, University of Rouen Normandy, MARC BRACHET, Ecole Normale Superieure Paris, QUTE-HPC COLLABORATION — We solve numerically the Gross-Pitaevskii (GP) equation to simulate the dynamics of Quantum Turbulence (QT) in a periodic box. This intends to model the behaviour of superfluid helium in the low-temperature regime, therefore a viscous-free flow. Simulations are performed with a spectral code solving the GP equation using MPI-OpenMP parallel programming. We assess the effect of different initial conditions on the statistical behaviour of the flow, through both spectra and structure functions. Closures for non-linear energy transfer terms are proposed and validated, mainly based on vortex reconnection mechanism. Analogies and differences between QT and classical turbulence are drawn.

5:19PM B08.00004 A Laser system for flow field imaging in superfluid helium using He₂⁺. SO SUZUKI, VOLKER SONNENSCHEIN, TAKUMI MARUYAMA, SHINICHIRO WAKI, HIDEKI TOMITA, YOSHIYUKI TSUJI, TETSUO IGUCHI, Nagoya University — For visualization of the flow field in superfluid Helium (He II), He₂⁺ excimer can be traced by using Laser induced fluorescence (LIF). In our group the proposed He₂⁺ excimer generation method is based on the neutron absorption reaction of naturally abundant $^3$He in Helium. Small He₂⁺ clusters generated by this method are then available for 3D LIF imaging. By applying this method, we already confirmed successful generation of He₂⁺ excimers using our laser system. In this study, for successful visualization of He₂⁺ excimer images in superfluid Helium, the required laser parameters, such as f intensity, repetition rate and wavelength were investigated. For systematic characterization of these, an offline system based on a high voltage discharge for excitimer generation is being set up to provide a more intense and accessible source of excimers, not requiring the use of a neutron beam.

Saturday, November 23, 2019 4:40PM - 6:11PM – Session B09 Aerodynamics: Rotating Wing 213 - Bo Cheng, Penn State University

4:40PM B09.00001 Scaling arguments for the radial vorticity advection and the radial planetary vorticity tilting in the leading-edge vortex of revolving wings¹. NATHANIEL WERNER, Penn State University, JUNSHI WANG, HAIBO DONG, University of Virginia, BO CHENG, Penn State University — Within the leading-edge vortex (LEV) of a revolving wing, planetary vorticity tilting (PVTr) can partly remove the radial vorticity generated by advection, a mechanism that relates the effects of Coriolis acceleration, spanwise flow, and the tilting of the planetary vorticity. It has been shown previously that the non-dimensional PVTr scales independently with Aspect Ratio (AR) while the advection scales inversely with AR, suggesting that separate scalings should be applied to these two terms. This study continues the previous investigation, with the goal of finding the correct scaling of the radial vorticity advection with the AR. The wing AR is changed by increasing the wing span and keeping the wing chord length constant; in this process we either keep the wing tip velocity constant (i.e., keeping the wing-chord-based Reynolds number constant) or keep the wing angular velocity constant (i.e., keeping the spanwise local Reynolds number constant). For both cases, we show that the correct length scale for the advection is wing span instead of wing chord (as for the PVTr), while both the advection and the PVTr have the tip velocity and planetary vorticity (or wing angular velocity) as the velocity and vorticity scales.

¹NSF CMMI 1554429

4:53PM B09.00002 Hover Predictions Using a High-Order Discontinuous Galerkin Off-Body Discretization¹, KURSAT KARA, Oklahoma State University, MICHAEL BRAZELL, ANDREW KIRBY, University of Wyoming, EARL DUQUE, Intelligent Light, DIMITRI MAVRIPLIS, University of Wyoming — Hover performance of a four-bladed Sikorsky S-76 is studied using a high-order discontinuous Galerkin (DG) off-body discretization. Time accurate Navier-Stokes calculations are performed using the WAFKE3D code which combines solution technologies in a multi-mesh, multi-solver paradigm through a dynamic overset framework which employs NSU3D as a near-body solver and dg3est as an off-body solver. The rotor with swept-tapered tip is simulated. The tip Mach number was 0.65, and the Reynolds number based on the reference chord was 1.2 million. A constant coning angle of 3.5° is applied. Effect of time step size and sub-iterations on the integrated parameters are investigated. Convergence results are presented. The figure of merit is calculated and compared with available data in the literature, and good agreement is found.

¹Computer time was provided by the NCAR-Wyoming Supercomputer Center (NWSC) and the University of Wyoming Advanced Research Computing Center (ARCC).
5:06PM B09.00003 Numerical simulation of a rotating blade using a flat-plate airfoil at low Reynolds numbers for Mars helicopter

DAICHI OGASAWARA, MAKOTO SATO, Kogakuin University, HIDEAKI SUGAWARA, Ryosy Systems Co., Ltd., YASUTADA TANABE, Japan Aerospace Exploration Agency, KOTARO SATO, Kogakuin University — To realize a high-performance rotor for a Mars helicopter, the aerodynamic performances and flow characteristics around a rotating blade using a flat-plate airfoil at low Reynolds numbers have been investigated. Numerical simulations have been conducted using a CFD solver of rFlow3D, which has been developed in JAXA for a rotorcraft simulation. The ambient pressures are set to 100 kPa, 50 kPa, 10 kPa, and 5 kPa, corresponding to the Reynolds numbers of 77000, 39000, 7700, and 3900 based on the blade tip velocity and the tip chord length respectively. The thrust and torque coefficients agree well with the previous experimental study for the cases with pitch angles up to 10 deg. The influences of the ambient pressure on the aerodynamic characteristics are not so significant in the cases with low pitch angles. On the other hand, the flow characteristics become highly different between the cases with the ambient pressure of 100 kPa and 5 kPa.

5:19PM B09.00004 Scaling effects on aerodynamic interactions of rotorcraft around boundaries

DARIUS CARTER, MEGAN MAZZATENTA, SHIJIE GAO, CARMELO DI FRANCO, NICOLA BEZZO, DANIEL QUINN, University of Virginia, LINK LAB COLLABORATION — The growth of the Micro Aerial Vehicle (MAV) industry is outpacing our understanding of how MAVs behave in cluttered environments. Search and rescue and product delivery — two key MAV applications — occur in tight, confined spaces filled with complex obstacles. Our current understanding of how MAVs interact with boundaries is based primarily on helicopter models, which were designed for high Reynolds-number single-rotor flows. To support better flow models of MAV-boundary interactions, we will measure the lift forces and flow of small quadrotors near a side wall, ground, ceiling, and water surface. To see how our results scaled, we measured differently-sized propellers in these same conditions. Using Particle Image Velocimetry, we quantified the momentum flux of the rotors and evaluated the assumptions made by the existing ground and ceiling models. Better physical models offer a way to predict MAV’s reaction to environmental disturbances, which is critical for certifying that MAVs can operate safely near or in cooperation with humans. Better models could offer physics-based situational awareness, which could reduce the need for heavy sensors and cameras and free up payload on small, lightweight MAVs.

5:32PM B09.00005 Propellers in Partial Ground Effect

JIELONG CAI, SIDAARD GUNASEKRAN, University of Dayton, MICHAEL OL, Folderol, LLC, ANWAR AHMED, Auburn University — The classical result for propellers (or any rotating wing) operating parallel and in close proximity to an unbounded flat-plate, is increase in thrust and decrease in power-required, for a given rotation-rate. We examine extreme cases, where the ratio of ground-proximity to propeller-diameter is 0.1 or less. We also reverse the propeller direction, for a ceiling effect. The limiting case for small ground separation is halving of power-required. However, this depends strongly on the ratio of propeller pitch to diameter. For large ratios (approaching 1), ground-effect offers almost zero benefit. For small ratios (on the order of 0.5), best results are obtained. We also consider a finite ground-plane as a circular disk. For a ratio of disk diameter to propeller diameter of 0.5, ground-effect is nil, while for a ratio of 1, full ground-effect is restored. Flow visualization gives the explanation: there is a circular time-averaged dividing streamline on the ground-plane, within which the projection of the flow is swirling, but outside of which the flow is radial. For ground-plate-disks of diameter smaller than this dividing streamline, propeller thrust is measured to resemble that in free-air, while for larger disks there is a strong ground-effect.

5:45PM B09.00006 Investigating Effects of Cracked Blade under Various Rotor Speed on Aerodynamic Characteristics in 1.5 Stage GE-E3 Gas Turbine

THANH DAM MAI, MYUNG GON CHOI, YUMIN KIM, JAIYOUNG RYU, Department of Mechanical Engineering, Chung Ang University, Seoul, 06974, Republic of Korea — The variation in revolutions per minute (RPM) has significant effects on dynamic behaviors, the flow characteristics, and the heat transfer in gas turbine. Coupled with cracked blade conditions, it can be speculated to have more dramatic effects on the overall performance. This is the first study to address both RPM variation and cracked rotor blade condition in three-dimensional unsteady gas turbine simulation. Reynolds-averaged Navier-Stokes (RANS) equation is used with k-ω SST turbulence closure model to solve high-speed, high-pressure compressible flow in GE-E3 gas turbine. Numerical cases are selected with RPMs of 4000, 3600, 3200, and 2800 under same cracked blade conditions. As a result, average temperature and heat flux on the blade surface are found to have inverse relations with RPM. Pressure overshoot occurs at greater RPM changes, but significant drop in average temperature and heat flux is observed at 4000 RPM. Moreover, it is also found that crack condition has significant effects on the aerodynamic behavior of compressed gas in high pressure gas turbine.

5:58PM B09.00007 An Experimental Investigation on Drone Propellers Operating Under Icing Conditions

ZHE NING, YANG LIU, Iowa State University, HONGWEI MA, BeiHang University, HUI HU, Iowa State University — An experimental study was conducted to investigate the dynamic ice accretion process over the surfaces of typical drone propeller blades and to characterize the detrimental effects of ice accretion on the performance of the Drone propeller in terms of thrust generation and power consumption. The experimental study was conducted in the Icing Research Tunnel of Iowa State University (i.e., ISU-IRT) with a commonly-used, commercially-available Drone propeller exposed in frozen-cold incoming airflow under various icing conditions usually encountered by Drones in winters (i.e., under both rime and glaze icing conditions). In addition to revealing the transient ice accreting process over the surfaces of the rotating propeller blades by using a “phase-locked” imaging technique with a high-resolution imaging system, the dynamic thrust force generated by the Drone propeller was also measured simultaneously along with the required power inputs to drive the Drone propeller during the dynamic ice accreting process. The time-resolved aerodynamic force measurements and power consumption data were correlated with the acquired snapshots of the instantaneous ice accretion images to gain further insight into the underlying icing physics pertinent to Drone icing phenomena.

Saturday, November 23, 2019 4:40PM - 6:11PM – Session B10 Vortex Dynamics and Vortex Flow: Simulations

3A - Monika Nitsche, University of New Mexico
4:40PM B10.00001 Numerical study of polarized viscous vortex reconnection, JIE YAO, FAZLE HUSSAIN, Texas Tech University — Polarized vortical structures (i.e. with axial flow, hence coiled vortex lines) are generic to turbulent flows; hence studying their dynamics and interactions is essential to understanding turbulence phenomena. Vortex reconnection is a frequent event in turbulent shear flows and play an important role in energy cascade, mixing and noise generation. To quantify the polarization effect on vortex reconnection, direct numerical simulation of two anti-parallel helical vortex tubes is performed for vortex Reynolds numbers ($ \equiv \text{circulation/viscosity} \geq 9,000$ and initial swirl numbers $q \equiv \text{peak azimuthal velocity/peak axial velocity} \in [4, 0.75]$). For both the non-polarized and polarized cases, the reconnection event is delayed as polarization strength increases (i.e. $q$ decreases), but with a higher circulation transfer rate during reconnection. Compared with the unpolarized case, enstrophy and energy dissipation rates are suppressed for weaker polarized ($q=1.5$) cases, but surprisingly enhanced for strong polarized ($q=1.5$) cases. In addition, increasing the polarization strength alters the energy spectrum in the inertial range with a scaling varying from $k^{-5/3}$ for the unpolarized case to $k^{-7/3}$ for the strongly polarized cases. Hence polarization is found to significantly alter vortex reconnection dynamics.

4:53PM B10.00002 The Influence of Reynolds Number on the Dynamics of Wing-Tip Vortices, TOM SMITH, YIANNIS VENTIKOS, University College London — Tip vortex flows are of considerable interest across a range of technologies and can be significant noise sources, particularly in hydrodynamic applications where tip-vortex cavitation can occur. There are still many open questions regarding the dynamics of this type of flow including Reynolds scale effects and the dynamics of wake-like and horseshoe vortex interactions. In this study, we investigate the Taylor–Green vortex (TGV) and Direct Numerical Simulations to study the vortex roll-up process in laminar foils at low and moderate Reynolds numbers. Grid convergence is achieved to improve confidence in the accuracy of the simulations and to develop a better understanding of the mesh requirements for this type of flow. A detailed analysis of the roll-up process is carried out, highlighting significant differences in the flow as the Reynolds number increases. At low Reynolds numbers, a single laminar vortex forms with a very low axial velocity in the core. Higher Reynolds numbers see the emergence of multiple vortices which merge in the near wake. The magnitude and longitudinal position of the minimum pressure is also found to depend on the Reynolds number, which has important consequences for cavitation predictions and scaling.

5:06PM B10.00003 Formation and Evaluation of Vortex Rings from Saddle Shape Nozzle, VAHID SADRI, SHELLY SINGH-GRYZBON, ZHENGLUN WEI, AJIT P YOGANATHAN, Georgia Institute of Technology — The mitral valve (MV) is a complex structure with a saddle-shaped annulus, separating the left atrium and left ventricle (LV). During rapid filling of the LV, a three-dimensional asymmetrical vortex ring forms downstream of the annulus. In this study, we investigated the formation mechanism and evolution of vortex rings from saddle-shaped nozzles using direct numerical simulations. A normal human mitral annulus was used to make the saddle-shaped nozzle geometry. The flow was simulated at a jet Reynolds number of 2,000 (based on hydraulic diameter and jet velocity) with jet pulse length-to-hydraulic diameter ratio ($L/D_h$) ranging from 1 to 6. It was found that the vortex ring from saddle-shaped nozzles has an oscillatory deformation while propagating, which causes the ring to undergo axis-switching. Furthermore, ambient fluid entrainment during vortex ring formation feeds to the main vortex structure, causing circumferential flow that splits the main vortex into smaller portions around the circumference. Additionally, the vortex formation number calculated for low stroke ratio cases.

5:19PM B10.00004 Evolution of vortex-surface fields in the flow past a finite plate, WENWEN TONG, YUE YANG, College of Engineering, Peking University — We investigate the evolution of the vortex-surface field (VSF) in the three-dimensional flow past a finite plate at the Reynolds number of 300, aspect ratio of 2, and angle of attack of 30 degrees. The VSF method is extended to complex flows with an immersed boundary by adding a source term in the VSF evolution equation. The VSF iso-surfaces display that near-plate vortex surfaces first roll up from plate edges, and then form hairpin-like structures near the leading edge and semi-riblet structures near plate tips and in the wake. We quantitatively distinguish two types of vortical structures by null points of streamwise vorticity on VSF isosurfaces, and refer them to as the leading edge vortex (LEV) and tip vortex (TV). The VSF characterizes that the development of the LEV near tips is suppressed by the finite growth of TV. In the wake region, helical vortex lines are generated and their geometry and impulses are quantified based on the VSF isosurfaces for TV.

5:32PM B10.00005 Controlling vortex breakdown through heat addition and extraction, XIAO ZHANG, University of Maryland, JOSEPH CHUNG, University of Maryland, College Park, CAROLYN KAPLAN, University of Maryland, ELAINE ORAN, Texas A&M University — This work examines how heat addition and extraction can be used to control the modes of vortex breakdown. Three-dimensional, unsteady simulations of gaseous vortex breakdown were carried out by solving the unsteady Navier-Stokes equations. Different modes of vortex breakdown were obtained by matching swirl and Reynolds numbers from the literature. Then, heat was either extracted or added within the vortex core to quantify the influence of non-adiabatic conditions. The results show that a critical value of heat addition will force the double helix vortex to transition to a spiral and then to the double helix mode of breakdown. Heat addition with the double helix mode, however, will force the double helix to transition to a columnar vortex, entirely bypassing the spiral mode. We discuss these results and other findings related to the bubble mode of breakdown.

5:45PM B10.00006 Role of helicity in vortex breakdown, SAMEEN A, MANJUL SHARMA, Dept. of Aerospace Engg., Indian Institute of Technology Madras, Chennai 600036, India — We investigate the bubble-type vortex breakdown flow numerically with a model problem of flow inside a cylinder with top rotating lid (also known as Vogel-Escudier flow). The parameters of the flow are $Re = \omega R^2/\nu$ and aspect ratio $\Gamma = H/R$, depending on which flow exhibits steady or unsteady breakdown bubble topologies. We find that negative helicity density is generated by the rotating top lid and is injected in the bulk of the flow at a critical value of the Reynolds number in the event of vortex breakdown. The flow also shows two-dimensional-three-dimensional (2D–3D) characteristics for which the helicity density is decomposed into $r,z$-component ($h_{r,z}$) and out-of-the-plane component ($h_{\theta}$). We find that the topology of the breakdown bubble correlates directly to the decomposed helicity $h_{r,z}$. Using only the decomposed helicity, $h_{r,z}$, complete breakdown bubble is reconstructed for non-axisymmetric flows. This correlation indicates that the vortex breakdown is the interplay between the axial component of velocity and the azimuthal component of vorticity which are characterized by $h_{r,z}$.

5:58PM B10.00007 Accurate evaluation of near-singular integrals in vortex sheet and Stokes flow, MONIKA NITSCH, University of New Mexico — Inviscid vortex sheet or viscous Stokes flow can be efficiently computed using boundary integral formulations, which describe the fluid velocity by integrals over interfaces bounding fluid regions. For points off the interface, the velocity is given by singular integrals, whose computation is well understood. However, for points not on the interface, but near it, the velocity is given by near-singular which are difficult to compute. This talk presents a simple method to accurately compute these integrals. It is based on approximating the integrand by functions that capture the near-singularity and can be integrated exactly. The method is quite general and is applied here to planar vortex sheet and axisymmetric Stokes flow.
Cost of wall modeling for the two wall models will be discussed. Model are conducted. Accuracy of the WMLES calculations will be discussed in terms of prediction quality of key mean-flow statistics at two

\[ \text{Re} = 4000 \]

where a skewed mean velocity profile is generated as TBL along the floor of a square duct deflects through a 30° bend. The experiment of Schwarz & Bradshow (J. Fluid Mech. (1994), vol. 212, pp. 183-209) is considered, have not been assessed in such nonequilibrium flows, where some of the key modeling assumptions are deemed invalid (e.g., unidirectional flow, turbulent boundary layers (TBL) in nature and realistic geometries of engineering applications. Wall models for large-eddy simulation (LES) wall-resolved simulations of nonequilibrium turbulent boundary layers is constructed, including scenarios of adverse/favorable pressure gradient and heated/cooled walls. The non-equilibrium forcing is spatially diffuse, providing significantly large regions where equilibrium scaling laws cannot be reasonably assumed in the inner layer, and necessitating non-equilibrium models for inner-layer accuracy. A database of wall-modeled simulations is then constructed to assess the model ability to reproduce non-equilibrium effects in both the inner and outer flow. Several model classes are employed including ODE, algebraic, and dynamic slip variants. The favorable performance of several new non-equilibrium models of algebraic complexity (efficient and easy to implement) is assessed relative to the equilibrium models and benchmark wall-resolved simulations.

5:06PM B11.00003 Wall model for large eddy simulations accounting for particle effect. 1

5:19PM B11.00004 Equilibrium/Non-Equilibrium Wall-Modeled LES of Airfoil Stall Phenomena at High-Reynolds Number

This is presented by the authors at the 51st AIAA Fluid Dynamics Conference, 23-26 June 2019, San Diego, CA, USA. The presented work is supported by the Japan Aerospace Exploration Agency (JAXA).

1This research was supported by NASA (80NSSC18M0155) and the Office of Naval Research (N00014-16-S-BA10).
5:45PM B11.00006 Assessment of Wall-Modeled LES for Turbulent Boundary Layers with Heated/Cooled Wall¹, RYO HIRAI, SOSHI KAWAI, Department of Aerospace Engineering, Tohoku University — In this talk, we first investigate the effects of wall heat flux induced by heated and cooled walls in zero-pressure-gradient flat-plate turbulent boundary layers by using wall-resolved large-eddy simulation (LES). Based on the wall-resolved LES database, we then assess the capability of the equilibrium wall model (Kawai and Larsson, PoF, 2012) for predicting the thermal turbulent boundary layers. By considering the behaviors of density and viscosity variations in the inner-layer of the thermal boundary-layer, one source of the major errors induced by the existing model is analyzed and a method that allows for the errors to be removed is proposed. Additionally, we also seek the possibility of further improvements in the wall model by modifying the mixing-length model based on the scaling laws derived from the analysis of the wall-resolved LES database.

5:58PM B11.00007 A near-wall eddy viscosity for compressible turbulent flows based on velocity transformation with application to wall models, PRAHLADH S. IYER, National Institute of Aerospace, PEDRO S. VOLPIANI, JOHAN LARSSON, University of Maryland, College Park, SERGIO PIROZZOLI, Sapienza University of Rome, MUJEEB R. MALIK, NASA Langley Research Center — A near-wall eddy viscosity is derived for zero-pressure gradient compressible turbulent flows based on a velocity transformation kernel. This is only valid in the inner layer of the flow with application to wall models. A priori analysis is performed using high-speed Direct Numerical Simulation (DNS) databases of turbulent boundary layers and channels over a range of Mach numbers and thermal conditions using the new formulation to assess its accuracy, and compare it with existing eddy viscosity models. Preliminary results are encouraging, and indicate that the errors in the wall model prediction is directly correlated with the error in the velocity transformation. More specifically, the eddy viscosity obtained with the proposed methodology and using the recent compressible velocity transformation of Volpiani et al. (2019) yields accurate results for supersonic and hypersonic turbulent boundary layers.

Saturday, November 23, 2019 4:40PM - 5:58PM – Session B12 Separated Flows: Control 303 - Amy Lang, University of Alabama

4:40PM B12.00001 Reversing Flow Formation Induced by an Increasing Adverse Pressure Gradient in a Separating Laminar Boundary Layer¹, ANDREW BONACCI, AMY LANG, LEO SANTOS, University of Alabama — Reversing flow development in a laminar boundary layer is a determining factor in the development of dynamic stall. It has been demonstrated that shark scales are capable of being bristled by reversing flow leading to a passive mechanism for separation control. An investigation of the formation of the reversing flow over a smooth surface is key to understanding this passive flow-actuated bio-inspired separation control mechanism. A water tunnel facility is utilized to generate a separated region by using a rotating cylinder to induce an increasing unsteady adverse pressure gradient over a smooth flat plate. Growing the laminar boundary layer to a thickness of about 10 mm and Reynolds numbers of 1.67*10⁵ to 2.98*10⁵ makes the separation region more measurable with DPIV. Results are analyzed for reversing flow development in size and magnitude to better understand the viscous development of the separation point as a function of the strength and timescale of the increasing adverse pressure gradient.

4:53PM B12.00002 Effect of perimetric suction at the rear of a square-back bluff body on the bi-stable dynamics of the wake flow¹, LUC PASTUR, ENSTA Institut Polytechnique de Paris, France, EN-CHI HSU, Institute of Mechanical Sciences and Industrial Applications ENSTA, Institut Polytechnique de Paris, VLADIMIR PAREZANOVIC, Khalifa University of Science and Technology, Abu Dhabi, UAE — Wake flows behind 3D bluff bodies are known to exhibit random switches between two mirror reflectional symmetry-breaking wake flows each associated with an increase of the drag. Consequently, it may be desirable to symmetrize the flow, if the symmetrization would consist in stabilizing the unstable symmetric flow state associated with a lower drag. One attempt in this direction may consist in steadily blowing symmetrically through perimetric slits at the rear of the body. However, it was recently shown that this mode of actuation could not symmetrize the flow. The present work is a preliminary investigation of the effect of a steady symmetric perimetric suction at the rear of the body, among other modes of actuation of the wake flow. For moderate flow rates, it is found that the transitions between the two states are promoted, indicating that the actuator has authority on the flow bistability. The resulting symmetrization of the probability distribution function of the pressure gradient is accompanied by a decrease of the base pressure, together with the slight reduction of the bubble length, as revealed by rear pressure and PIV measurements.

5:06PM B12.00003 Control of the reflectional symmetry breaking mode of a square-back bluff body wake using a sweeping jet actuator\footnote{This work has been supported by the Khalifa University of Science and Technology under Award No(s). FSU-2018-21 and CIRA-2019-025.}, VLADIMIR PAREZANOVIC, ABDUL RAOUF TAJIK, Khalifa University of Science and Technology, LUC PASTUR, IMSIA-ENSTA Institut Polytechnique de Paris — The wake of a square-back 3D bluff body is dominated by a stochastic switching between two reflectional symmetry breaking wake flows\footnote{M. Grandemange et al., Phy. Rev. E 86, 035302}. The two mirror wakes are associated with an increased drag. We attempt to symmetrize the wake using a Sweeping Jet (SJW) actuator located at the top of the bluff body base. Arrays of SWJs have been used to reduce the drag of the 3D bluff body by reattaching the flow to an angled back\footnote{M. Metka and J. W. Gregory, J. Fluids Eng. 137 (5), 051108} or to trailing edge flaps\footnote{J. Schmidt et al., Exp. Fluids 56, 151}. In our study, only a single SJW is used, and its exit nozzle almost spans the entire width of the bluff body base. The SJW produces a jet which oscillates horizontally, along the same direction of the bistable wake switching. The sweeping motion of the jet is intended to interact with the wake state switches, which may lead to a symmetric wake. Base pressure measurements reveal a wake locked in a symmetric state in the horizontal plane, for a certain range of actuator mass flow rates. This result is accompanied by a change in the vertical orientation of the wake.

5:19PM B12.00004 Elimination of velocity deficit behind a cylinder using reinforcement learning\footnote{RGC of Hong Kong under GRF (Project No. 15214418) and The Hong Kong Polytechnic University (Project No. G-YBXXQ)}, FENG REN, HUI TANG, The Hong Kong Polytechnic University — In this study, we present an active flow control strategy through deep reinforcement learning (DRL) for eliminating the velocity deficit in the wake of a circular cylinder. A group of windward-suction-leeward-blowing actuators are adopted. Their individual velocities are automatically adjusted by the DRL agent through feedback signals from a downstream sensor array. Simulations are conducted using a GPU-accelerated lattice Boltzmann solver with multi-block mesh partition. The high-dimensionality and non-linearity features of this problem make it challenging to explicitly determine the control strategy. By adopting the DRL, the agent can learn from the time sequences of the sensors, actuators and a specified reward function through trials and errors, and finally converge and determine the optimal control strategy. Results show that the well-trained control strategy can eliminate 99.7% of the velocity deficit. The policy is further transferred for fluid-structure interaction situations, and results based on four representative cases show that the transferred control strategy is robust and can effectively eliminate the velocity deficit by around 96%. Overall, the current study offers an innovative view that could potentially help underwater vehicles achieve low detectability.

5:32PM B12.00005 DSMC Simulation of Flow Past a Circular Cylinder at Re = 100, J.R. TORCZYNSKI, M.A. GALLIS, Sandia National Laboratories — The Direct Simulation Monte Carlo (DSMC) method is used to simulate vortex shedding in the flow of a gas past a circular cylinder at Re = 100, Ma = 0.1 (incompressible), and Kn = 0.00162 (continuum). Sandia’s DSMC code SPARTA is used. The domain is 5 diameters upstream, 10 diameters downstream, and 5 diameters on both sides and is meshed with 0.72 billion square cells with sides of 1/4 mean free path. Each cell contains $10^4$ particles, for 72 billion particles total. The time step is 1/3 of the mean collision time. Simulations are run on Sequoia, an IBM Blue Gene/Q petascale supercomputer at LLNL. The Kármán vortex street arises without using any perturbation, and the lateral force on the cylinder is periodic with a Strouhal number of 0.175. Sandia National Laboratories is a multimission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-NA0003525. This paper describes objective technical results and analysis. Any subjective views or opinions that might be expressed in the paper do not necessarily represent the views of the U.S. Department of Energy or the United States Government.

5:45PM B12.00006 On The Flows Of Low-Aspect Ratio Rotating Circular Cylinders\footnote{Air Force Office of Scientific Research (AFOSR)}, HISHAM SHEHATA, ALBERT MEDINA, MATTHEW ROCKWOOD, Air Force Research Laboratory, Wright-Patterson AFB, OH — A low-aspect ratio circular cylinder is placed on a laminar boundary layer plate in a wall-normal orientation, and rotated about its respective axial coordinate. It is found that the rotary motion of the cylinder may disrupt the symmetry of mainstay vortices associated with a static low-aspect ratio pin, resulting in a dominant streamwise vortex formation. Such formation stems from asymmetry of the near body wake, induced by cylinder motion and downwash effects at the free-end of the cylinder. The influence of cylinder aspect ratio, cylinder height to boundary layer thickness, and rotational rate are explored in detail through volumetric reconstruction of the flow field via stereoscopic particle image velocimetry (SPIV).

4:40PM B13.00001 Magnetic Braking of Jovian Jet Flows, ASHNA AGGARWAL, UCLA, SUSANNE HORN, Coventry University, JONATHAN AURNOU, UCLA — The azimuthally-directed jet flows of the gas giants, Jupiter and Saturn, are amongst their most dominant surface features. Recent Juno gravity measurements have inferred that the zonal jets of Jupiter extend from the weather layer, where they are directly observed, down at least 3,000 km deep into the H-He molecular atmosphere. In addition, Jupiter’s electrical conductivity increases as the molecular envelope transitions to a liquid metal. As electrical conductivity increases, the strength of magnetic forces grows, acting as a resistive brake on the jet flows. We have developed a pseudo-spectral code that solves the Cartesian Navier-Stokes equations in 2-D with buoyancy and a quasi-static magnetic field to quantify the process of magnetic braking, thought to truncate the Jovian jets. We will present the results of a suite of direct numerical simulations (DNS) of shearing convection, similar to Goluskin et al., (J. Fluid Mech. 759, 360, 2014), where we vary the strength of an imposed transverse magnetic field. Depending on the value of the magnetic field, the jets are damped, strongly intermittent, or fully suppressed.
4:53PM B13.00002 The Elbert Subrange of Magnetostrophic Rotating Convection, SUSANNE HORN, Coventry University, JONATHAN AURNOU, University of California, Los Angeles — Classical linear stability analysis shows that convection subjected to rotation and a magnetic field is most easily excited when Coriolis and Lorentz forces are approximately in balance and in the form of a large-scale stationary bulk mode. Since estimates for Earth also suggest that the outer liquid metal core is in this so-called magnetostrophic state, there is a long-held belief that these modes optimise planetary magnetic field generation. But a single-mode theory is not likely to be geophysically realistic. Instead, liquid metal flows are characterised by pronounced multimodality with a mix of stationary, oscillatory, and boundary-attached modes. In fact, Donna Elbert (cf. Chandrasekhar, 1961) discovered that there is subrange of magnetostrophic rotating convection where two types of stationary modes co-exist: a small-scale geostrophic mode and a large-scale magnetostrophic mode. The parameter space for this subrange coincides with the one for planetary cores, suggesting a crucial link to the magnetic field generation in geo- and astrophysical objects. Here, we revisit linear stability results and further use nonlinear direct numerical simulations to verify which onset characteristics, such as length scales and frequencies, carry over to higher supercriticalities.

5:06PM B13.00003 Experimental study of the non-linear saturation of the elliptical instability: inertial wave turbulence versus geostrophic turbulence1, THOMAS LE REUN, BERNARD FAVIER, MICHAEL LE BARS, IRPHE, Aix-Marseille Universitat, ERC FLUDYCO TEAM — We present an experiment of the turbulent saturation of the flow driven by parametric resonance of inertial waves in a rotating fluid. An ellipsoid filled with water is brought to solid-body rotation and then undergoes harmonic modulation of its rotation rate. This triggers the exponential growth of a pair of inertial waves via the elliptical instability. As the instability reaches non-linear saturation, it creates a turbulence where energy is injected into the resonant waves only. Depending on the amplitude of the rotation rate modulation, two different saturation states are observed. At large forcing amplitudes, the saturation flow mainly consists of a steady, geostrophic anticyclone. Its amplitude vanishes as the forcing amplitude is decreased while remaining above the threshold of the elliptical instability. Below this secondary transition, the saturation flow is a superposition of inertial waves which are in weakly non-linear resonant interaction, a state that could asymptotically lead to inertial wave turbulence. The present study is an experimental confirmation of the model of Le Reun, PRL (2017) who introduced the possibility of these two turbulent regimes. The transition between these two regimes and their relevance to geophysical applications are finally discussed.

5:19PM B13.00004 How the Great Red Spot of Jupiter Stays Alive while Losing Energy through Viscous and Radiative Dissipation, AIDI ZHANG, PHILIP MARCUS, UC Berkeley — During the last decade, the cloud cover over the Great Red Spot (GRS) of Jupiter has shrunk significantly. This observation, along with recent observations that the GRS has been repeatedly shedding large (100,000 km$^2$) chunks of itself, has caused many planetary scientists to speculate that the GRS will vanish in the next 10 years. We argue against that hypothesis and demonstrate that GRS, which is a large anticyclone, maintains itself with a weak (and not directly observable) secondary circulation that is consistent with all of the observations. Numerical simulations of the anelastic ideal gas equations are used to show that this secondary circulation both re-energizes the GRS and creates new anti-cyclonic vorticity via baroclinic dynamics that can only exist in a vertically stably-stratified, rotating atmosphere. The secondary circulation brings energy from the atmosphere outside the GRS into its interior. The energy flux into the GRS balances the loss of energy of the GRS from viscous and radiative dissipation. The rate of viscous losses agrees with the rate of loss of stored angular momentum and thermal energy due to radiative damping. Without the secondary circulation of the GRS, radiative damping would cause the GRS to decay in 4-5 years.

5:32PM B13.00005 A quasi-geostrophic thermally driven model for rapid dynamics in Earth’s core, MEREDITH PLUMLEY, ANDREW JACKSON, ETH Zurich, STEFANO MAFFEI, University of Leeds — Simulating the physics of Earth’s core remains an elusive challenge that precludes numerical solution of the full governing equations. Model reduction must be embraced to study the dynamics occurring in the core. One alternative for rotating flows is to adopt a columnar approximation for the velocity field, sometimes referred to as the quasi-geostrophic approximation. This technique is used to derive a completely newmodel for the rapid dynamics in thermally driven convection on the equatorial plane by using axial averages. We show that the onset of thermal convection found using local theory applied to this model agrees quantitatively with the values found in full numerical investigations and asymptotic theory. Time evolution results from this model can provide insight into the dynamics on short timescales in the core. We investigate the scaling laws of supercritical convection in parameter regimes unachievable in 3-D models.

5:45PM B13.00006 Machine learning predictions for magnetic field time evolution in a Three-Meter liquid sodium spherical Couette experiment1, ARTUR PEREVALOV, RUBEN ROJAS, BRIAN HUNT, DANIEL LATHROP, University of Maryland College Park — The source of the Earth’s magnetic field is the turbulent flow of liquid metal in the outer core and its interaction with the present magnetic field. Our experiment’s goal is to create an Earth-like dynamo to explore the mechanisms of generating magnetic fields and to understand the involved dynamics. Full numerical prediction is a challenging problem as it is strongly nonlinear and not computationally feasible to resolve. We present the implementation of various prediction techniques, including a reservoir computer deep learning algorithm, to probe the feasibility of using magnetic field data from the experiment to predict future measurements. The experiment is a three-meter diameter outer sphere and a one-meter diameter inner core model with the gap filled with liquid sodium. The spheres can rotate independently up to 4 and 14 Hz respectively, giving a Reynolds number up to $1.5 \times 10^8$. Two external electromagnets apply magnetic fields, while an array of Hall sensors measure the resulting magnetic fields. We use this data to train a reservoir computer to predict Hall sensor measurements and mimic waves in the experiment. Surprisingly, accurate predictions can be made for several magnetic dipole time scales. This shows that such a MHD systems behavior can be predicted.

1 NSF EAR-1417148 EAR-1909055
Our experiments aim to provide a deeper understanding of the turbulent convection and its interaction with magnetic fields in turbulent low Prandtl number flows as those in molten steel, aluminum or in geo- and astrophysical flows.

1Deutsche Forschungsgemeinschaft GRK 1567 and No. VO 2332/1-1

4:53PM B14.00002 Mixing in magnetohydrodynamic turbulence1. X.M. ‘SHINE’ ZHAI, Numeca-USA, P. K. YEUNG, KIRANRAVIKUMAR, Georgia Institute of Technology — Turbulence is characterized by its ability to efficiently promote scalar mixing, which occurs at the molecular level as large scale non-uniformities are broken into ever smaller pieces accompanied by a classical energy cascade. Yet for electrically conducting fluid subject to a strong magnetic field, anisotropy develops in all scales of turbulence and energy cascade is inhibited (Zhai & Yeung, PRF 2018). As a result, scalar mixing in magnetohydrodynamic (MHD) turbulence is expected to show distinctly different behaviors. We have performed direct numerical simulations of scalar mixing in MHD turbulence under mean scalar gradient. When a magnetic field is present, mixing of scalars in liquid metals, which has a Schmidt number of $O(0.01)$, is weakened as scalar variances grow more slowly. Variances of scalar gradients grow faster for less diffusive scalars, but gradient fluctuations in the direction of the magnetic field are suppressed. The largest simulations for passive scalars were performed at a resolution of $8192 \times 2048^2$ on a domain size of $32\pi \times (4\pi)^2$. The case of active scalars is also briefly addressed.

5:06PM B14.00003 Decay of turbulence in a duct with transverse magnetic field

OLEG ZIKANOV, University of Michigan - Dearborn, DMITRY KRASNOV, THOMAS BOECK, Ilmenau University of Technology, SEMION SUKORIANSKY, Ben-Gurion University of the Negev — Decay of honeycomb-generated turbulence in a duct with a static transverse magnetic field is studied via high-resolution direct numerical simulations. The simulations follow the experimental study of Sukoriansky et al., 1986, in particular the paradoxical observation of high-amplitude velocity fluctuations, which exist in the downstream portion of the flow when the strong transverse magnetic field is imposed in the entire duct including the honeycomb exit, but not in other configurations. It is shown that the fluctuations are caused by the large-scale quasi-two-dimensional structures forming in the flow at the initial stages of the decay and surviving the magnetic suppression. Statistical turbulence properties, such as the energy decay curves, two-point correlations and typical length scales are computed. The study demonstrates that turbulence decay in the presence of a magnetic field is a complex phenomenon critically depending on the state of the flow at the moment the field is introduced.

5:19PM B14.00004 Laboratory Measurement of Non-Rotating Magnetooconvection in Liquid Gallium: Wall-mode Onset and Supercritical Precessional Mode1. YUFAN XI, University of California, Los Angeles, SUSANNE HORN, Coventry University, JONATHAN AURNOU, University of California, Los Angeles — Magnetooconvection in the Earth’s molten outer core, driven by convection, generate a planetary-scale, nearly axial, dipole-dominated magnetic field. The behaviors of strongly turbulent convection in the presence of strong Lorentz forces are mostly unknown. Thus, we present results of laboratory experiments on non-rotating Rayleigh-Bénard convection of liquid gallium in the presence of a vertical magnetic field. Our heat transfer survey in a diameter-to-height aspect ratio $\Gamma = 1$ tank, with $10^6 < Ra < 10^9$ and $0 < Ch < 3 \times 10^9$, shows that the convection onset well below the predicted $Ra$ for an infinite fluid layer. Magnetooconvection in our finite cylindrical tanks likely onsets via stationery wall-attached modes (Houchens et al., 2002; Busse, 2008). In a $\Gamma = 2$ tank and with $Ra \approx 2 \times 10^9$, we vary the applied magnetic field corresponding to interaction parameter numbers $N$ from 0 to 10. Our thermal measurements show the existence of a novel precessional mode at $N \approx 0.5$ with electrically conducting boundaries (Cu), but not with electrically insulated boundaries (Teflon coated Al). This finding suggests the possibility of slowly traveling magneto-precessional modes attached to the electrically conductive boundaries of Earth’s outer core.

literature. A theoretical model is being sought to represent this interaction and predict its effect on the near field entrainment. 

Using conditional averaging, this organization was distinguished in the ring and braid region. For the excited jets, it agreed well with the organization of streamwise vortices from radial (in unforced case) to an azimuthal configuration that has been classically observed at low particle image velocimetry was performed at one and two diameters downstream of the nozzle. We varied the strengths of the axisymmetric where drop formation happens. In most views on jet shape and formation the role of surface tension is neglected; our experiments however demonstrate that both the ballistic and tip region of the jet are strongly decelerated by surface tension forces, that also affect the jet shape. 

Several theories exist relating jet shape and internal fluid motion, but none so far can describe all beautiful shapes remain incompletely understood. We perform PIV experiments to probe dynamic fluid motion inside an emanating jet to relate the fluid flow to the jet evolution and shape. 

demonstrate that both the ballistic and tip region of the jet are strongly decelerated by surface tension forces, that also affect the jet shape. Several theories exist relating jet shape and internal fluid motion, but none so far can describe all the different features of the jet. We find that for some experimental parameters that the jet acquires a large upward velocity in a small upward acceleration region located near the jet base due to collapse of a cavity formed during impact of the falling drop. The PV allows to distinguish three jet regions: a small acceleration region, a long ballistic region where fluid moves with a nearly constant momentum, and a jet tip region where drop formation happens. In most views on jet shape and formation the role of surface tension is neglected; our experiments however demonstrate that both the ballistic and tip region of the jet are strongly decelerated by surface tension forces, that also affect the jet shape. 

4:40PM B15.00001 Particle image velocimetry inside emanating jets to study jet shape and evolution. CEES VAN RIJN, DANIEL BONN. University of Amsterdam, BODJIE VAN BRUMMEN, JERRY WESTERWEEL. Technical University Delft, FLUID MECHANICS GROUP TUD COLLABORATION. — Jets resulting from drop impact on a fluid are a fascinating and remarkably robust phenomenon. However, their beautiful shapes remain incompletely understood. We perform PIV experiments to probe dynamic fluid motion inside an emanating jet to relate the fluid flow to the jet evolution and shape. Several theories exist relating jet shape and internal fluid motion, but none so far can describe all the different features of the jet. We find that for some experimental parameters that the jet acquires a large upward velocity in a small upward acceleration region located near the jet base due to collapse of a cavity formed during impact of the falling drop. The PV allows to distinguish three jet regions: a small acceleration region, a long ballistic region where fluid moves with a nearly constant momentum, and a jet tip region where drop formation happens. In most views on jet shape and formation the role of surface tension is neglected; our experiments however demonstrate that both the ballistic and tip region of the jet are strongly decelerated by surface tension forces, that also affect the jet shape. 

4:53PM B15.00002 A Tensor Formulation of the Lumley Decomposition Applied to the Jet Far-field. AZUR HODZIC, KNUD ERIK MEYER, Technical University of Denmark, WILLIAM K. GEORGE, Imperial College London, CLARA M. VELTE, Technical University of Denmark — A tensor formulation of the Lumley Decomposition (LD) is applied to the jet far-field which is analyzed in curvilinear coordinates. Fourier-based eigenfunctions along the streamwise direction are deduced directly from the LD, but only if a specific weighted inner-product space is chosen for the decomposition. A Galerkin projection of the turbulence kinetic energy (TKE) production term is then analyzed in order to quantify the TKE production capabilities of the eigenfunctions. It is shown that a wide range of mode- and wavenumbers exhibit similar rates of energy extraction directly from the mean flow, as hypothesized by [Winstrm 2009]. Data obtained from PIV measurements of the jet far-field then suggest that the energy transport between eigenfunctions is not strictly governed by the classical Richardson cascade model, but that a wide range of modes are at least partially able to circumvent this cascade. [Wänström 2009] Spatial decompositions of a fully-developed turbulent round jet sampled with particle image velocimetry. Ph.d. thesis, Chalmers University of Technology. 

This project has received funding from the European Research Council (ERC) under the European Unions Horizon 2020 research and innovation program (grant agreement No 803419). 

5:06PM B15.00003 The dynamics of streamwise vortices in high Re jets. JAHNAVI KANTHARAJU, DAAA, ONERA Meudon 92190, BENJAMIN LECLAIRE, LAURENT JACQUIN, DAAA, ONERA Meudon 92190 France — Streamwise vortices play an important role in the mixing and entrainment in the near field of jets. They are dynamically active structures that lead to additional flow features such as side jets and streaks. Their coexistence with and wrapping around the vortex rings suggest their possible influence on the rings as has been remarked in several studies. We present results supporting one such possible interaction between streamwise vortices and the axisymmetric \(\text{(} n = 0 \text{)}\) mode in round jets (Davoust et. al JFM 2012) at \(Re\) in the range of \(9.2 \times 10^3\) to \(3.5 \times 10^4\). High speed particle image velocimetry was performed at one and two diameters downstream of the nozzle. We varied the strengths of the axisymmetric mode relative to streamwise vortices through acoustic excitation. It is shown that as the axisymmetric mode is strengthened, there is a shift in the organization of streamwise vortices from radial (in unforced case) to an azimuthal configuration that has been classically observed at low \(Re\). Using conditional averaging, this organization was distinguished in the ring and braid region. For the excited jets, it agreed well with the literature. A theoretical model is being sought to represent this interaction and predict its effect on the near field entrainment.
5:19PM B15.00004 Three-dimensional Lagrangian statistics of a turbulent free-shear jet, BIANCA VIGGIANNO, Portland State University, THOMAS BASSET, ROMAIN VOLK, LAURENT CHEVILLARD, MICKAËL BOURGON, Laboratoire de Physique de l’ENS de Lyon, Raul BAYON CAL, Portland State University — A fundamental study of a free-shear jet is performed to investigate the highly anisotropic and inhomogeneous flow field through Lagrangian statistics. Experiments were conducted within a Lagrangian Exploration Module, an icosahedron apparatus, to facilitate optical access of three high speed cameras. This enables the generation of 3D particle trajectories by implementing stereoscopic particle tracking velocimetry and results in three component tracks of position, velocity and acceleration of the tracer particles within the vertically-oriented jet. The total measurement volume is 80 x 80 x 200 mm³, which includes over 50 nozzle diameters downstream, where the jet becomes self-similar. Lagrangian statistical analysis is performed to identify intermittent behavior at the centerline of the jet and at the turbulent/non-turbulent interface. Further, the applicability of Taylor’s frozen flow hypothesis is investigated.

5:32PM B15.00005 Non-equilibrium Turbulent/non Turbulent Interface velocity scaling in turbulent planar jets, GIOACCCHINO CAFIERO, Politecnico di Torino, JOHN CHRISTOS VASSIDILICOS, Imperial College London — We investigate the turbulent/non-turbulent interface (TNTI) of a turbulent planar jet using stereo-PIV and HWA. Following Zhou & Vassisilos (JFM 2017) we derive an expression for the entrainment velocity \( \frac{\nu_n}{\nu} \), where \( \nu \) is the streamwise coordinate, \( \nu \) is the streamwise velocity, \( A_T \) is the area of the turbulent region in a plane orthogonal to the mean flow, and \( L \) is the length of the TNTI in that plane. \( \nu_n \) can be expressed as \( \nu_n \sim L^{-\eta} \) where \( \eta \) is the jet width at \( x \). Our experimental results confirm Corrsin’s \( \eta \sim \nu/v \) (Corrsin 1955) is a characteristic interface thickness and \( \eta \) is the line interface’s fractal dimension. Non-equilibrium dissipation self-similar jet theory (Cafiero & Vassilicos PRSA 2019) predicts that \( \nu_n/\nu \) (where \( \nu \) is the Kolmogorov velocity) is a decreasing function of \( x \), which is at odds with the classical Corrsin scaling \( \nu_n \sim \nu \). Our experimental results confirm Corrsin’s \( \eta \sim \nu/v \) but also show that \( \nu_n/\nu \) is indeed a decreasing function of \( x \). Our measurements support the scaling \( \nu_n \sim \nu \) (\( \nu \) being \( \lambda \) the Taylor scale) predicted by our theory.

5:45PM B15.00006 Round and Plane, Turbulent, Twin Jets, TAYE MELAKU TADDESSE, JOSEPH MATHEW, Indian Institute of Science — Multiple jets are found in several applications such as fuel injection, smoke stacks, jets engines of aerospace vehicles, etc. Even a pair of round jets can have a distinctive development because, after the inevitable merging, there can be axis switching. While plane jet pairs may be expected to behave like a single plane jet after merger, significant differences have been observed in experiments. LES of parallel twin jets, round and plane, reveal the structure and mechanisms of these two types. The LES is by an explicit filtering method. The twin round jets are at a Reynolds number Re = 2.3 x 10⁵, based on diameter and mean velocity at exit. Distance between jet centers was 5 diameters. Close quantitative agreement with experiment was found on the development of mean profiles and spreading. Velocity fluctuations between the jets are weaker than those on the outer boundaries. Axis switching was observed. Twin plane jets were at \( Re = 8.75 \times 10^4 \) based on jet width, spaced 12 jet widths apart were also simulated. The enhanced growth rate of twin jets has been captured in the simulations.

5:58PM B15.00007 Mixing of temperature and helium in turbulent co-axial jets¹, ALAIS HEWES, LAURENT MYDLARSKI, McGill University — There are relatively few studies of turbulent multi-scalar mixing, despite the occurrence of this phenomenon in common processes (e.g. chemically reacting flows, oceanic mixing). In the present work, we study the mixing of two passive scalars (temperature and helium concentration) in turbulent co-axial jets using a novel, 3-wire, thermal-anemometry-based probe designed to simultaneously measure velocity, temperature, and concentration. We emphasize that unlike most previous investigations of multi-scalar mixing, the instantaneous velocity field is measured in addition to the scalar fields, as it is required to fully describe turbulent scalar mixing. Our experiments are performed in vertically oriented co-axial jets consisting of a central jet of helium and an annular flow of (unheated) pure air, emanating into a slow co-flow of (pure) heated air (similar to the experimental set-up of Cai et al. (J. Fluid Mech., 2011)). We present measurements made in the near field of the jets, including variances and scalar fluxes, and focus on the evolution of the flow of (unheated) pure air, emanating into a slow co-flow of (pure) heated air (similar to the experimental set-up of Cai et al. (J. Fluid Mech., 2011)). We present measurements made in the near field of the jets, including variances and scalar fluxes, and focus on the evolution of the flow of (unheated) pure air, emanating into a slow co-flow of (pure) heated air (similar to the experimental set-up of Cai et al. (J. Fluid Mech., 2011)).

Saturday, November 23, 2019 4:40PM - 6:11PM — Session B16 Advances in CFD Algorithms I 4c3 - Rajeev Jaiman, UBC

4:04PM B16.00001 Intersection-Based ALE for Radiation Hydrodynamics, PATRICK PAYNE, MARC CHAREST, HYEONGKAE PARK, Los Alamos National Laboratory — Many of the existing methods for Lagrangian hydrodynamics utilize staggered-grid hydrodynamic (SGH) algorithms. However, the fact that the momentum is defined by a nodal- and cell-centered coordinate,

4:53PM B16.00002 Robust data assimilation using mixed-norm optimization, SOUVIK GHOSH, Imperial College London, VINCENT MONSE, OLIIVIER MARQUET, DENIS SIPP, ONERA, France, PETER SCHMID, Imperial College London — Experimental data are often contaminated with outliers which in turn influence the quality of recovery in data assimilation techniques. We develop and present a computational framework based on mixed-norm optimization to determine flow fields from experimental measurements via a data-assimilation technique. More specifically, we use a variational adjoint-based methodology to balance a recovery error with a sparsity constraint, resulting in a saddle-point problem. The method shows promise in situations where only sparse measurements are available. Applications from mean-flow recovery at lower Reynolds numbers, as well as Reynolds-stress recovery at higher Reynolds numbers, will be presented.
This work was supported by the Center for Autonomous Systems and Technologies (CAST).
4:53PM B17.00002 Modeling rotor wakes of a quadrotor UAV in hovering mode\textsuperscript{1}, SEUNGCHEOL LEE, HUNGSON JOO, JOOHA KIM, Ulsan National Institute of Science and Technology, UNIST, Korea — For rotary-wing aircraft, predicting the locations of the rotor-tip vortices plays an important role in determining the rotor performance. Thus, there have been various attempts to model the rotor wake geometry for a single rotor. However, when these models are applied to multi-rotor UAVs, the interaction between rotor wakes, such as wake deflection, cannot be modeled. In the present study, we develop an empirical model that can predict the wake geometry for a quadrotor UAV in hover. The experiment is performed in a chamber at Re = 34,000, where Re is the Reynolds number based on the rotor chord length and the rotor-tip speed. By varying the normalized rotor separation distance (d/D) from 0.06 to 1.18, we directly measure the thrust force and the velocity field in the rotor wake using PIV, where d is the distance between adjacent rotor tips and D is the rotor diameter. With decreasing the normalized rotor separation distance, the extent of rotor-rotor interaction increases, and thus the wake center moves more to the center of UAV as the wake develops downstream. The wake geometry is predicted by modeling the locations of the wake center and the wake diameter as functions of the normalized rotor separation distance. Details will be discussed in the presentation.

\textsuperscript{1}Supported by NRF (2016R1D1A1B03933176, 2019R1F1A1064066), Research Fund (1.190011.01) of UNIST and Civil-Military Technology Cooperation Program (18-CM-AS-22).

5:06PM B17.00003 Characterization of Rotor-Rotor Aerodynamic Interactions for Free Flight Studies of Multirotor Systems\textsuperscript{1}, MARCEL VEISMANN, MORTEZA GHARIB, Caltech — As multirotor systems are increasingly utilized for academic as well as commercial purposes, their aerodynamics require precise identification for performance evaluation and more reliable predictive models. However, the interactions between closely arranged rotors have been given little attention. In order to account for the interactional effects on generated thrust, we developed an analytic expression derived from experimental data that is dependent on geometric and operational parameters, specifically rotor separation, rotational speeds, and Reynolds number. We find that the thrust reduction caused by the flow of neighboring rotors must be considered to accurately predict a multirotor system’s cumulative propulsive force. Using this analytical model, we aim to quantify rotor performance in various free flight conditions.

\textsuperscript{1}The presented material is based upon work supported by the Center for Autonomous Systems and Technologies (CAST) at the California Institute of Technology

5:19PM B17.00004 Experimental Measurement of Flow Field Around a Rotary Wing Unmanned Aircraft for Evaluation of Onboard Anemometer Placement\textsuperscript{1}, AYLSSA AVERY, SEABROOK WHYTE, JAMES BRENNER, VICTORIA NATALIE, JAMEY JACOB, Oklahoma State University — CLOUD-MAP is a collaboration between multiple universities to develop and evaluate unmanned aircraft technologies to place atmospheric sensors in otherwise hard to reach areas in the atmosphere. To determine the effectiveness of ultrasonic anemometers mounted on rotary wing aircraft, multirotor aircraft have been outfitted with sonic anemometers to measure windspeed and direction of winds aloft. The experiment maps the in-flow around a multirotor using multiple diagnostics, including PIV, ultrasonic anemometers, multi-hole probes, and impeller anemometers. Evaluation begins with flow measurements around a fixed single multirotor arm and followed up with multiple rotors with increasing fidelity for in-flight UAS. Multirotors are also placed in a wind tunnel and angled to simulate a sonic anemometer crosswind measurement. Comparisons with flight modes are made utilizing the OSU Gust and Shear Wind Tunnel Areas while validation tests are performed with tower mounted anemometers both at the Oklahoma Mesonet and the DOE ARM SGP Site. Areas of general quiescent flow are found absent of large scale disturbances or turbulent fluctuations. Results detail the accuracy of sonic anemometer measurements from mounted while on the multirotor in flight.

5:32PM B17.00005 Flight performance of autonomous quadrotors in von Karman wakes, KASEY LAURENT, JOSHUA SOLBERG, MARIGOT FACKENTHAL, GRACE DING, GREGORY BEWLEY, Cornell University — Natural environments are highly variable and present significant challenges for autonomous aircraft. As the size of aircraft decreases, they become more susceptible to flow disturbances and typical control schemes fail. An understanding of the effects of turbulence on flight becomes crucial when developing new control schemes to optimize the performance of smaller aircraft. We designed an experiment in which an autonomous controller flies a small quadrotor in the von Karman vortex street behind a cylinder in a wind tunnel. We varied controller parameters as well as properties of the flow, such as mean airspeeds up to 3 m/s and wake dimensions as well as flow time scales between 0.5 and 2 times the quadrotor dimensions and response times, to find relationships between the controller and the response of the quadrotor. We measured displacements and power consumption in flight in the wake and compared this to the performance of the quadrotor in quiescent flow. Finally, we compare to the behavior of the quadrotor in active grid turbulence, with turbulence intensities up to 26%. We find that the quadrotor dynamics are set by an interplay between the turbulence and the controller.

5:45PM B17.00006 Potential Flow Model for Wall Effects on Quadrotor UAVs\textsuperscript{1}, DMITRI CALOMIRIS, JOVAN NEDIC, McGill University — Solid surfaces are known to directly influence the flow surrounding propellers when they are close to each other by altering the thrust force. One of the most common potential flow models, developed by Cheeseman and Bennett, predicts the relative increase of a rotor’s thrust as a function of ground distance (for constant power operation), within four rotor radii (i.e. in ground effect). Recently, Sanchez-Cuevas et al. extended this single propeller model to a quadrotor, which experiences a much larger influence from the ground. However, no such characterization has been done for walls. A potential flow model to account for wall effects will be presented and the results compared to experimental data. Initial measurements have qualitatively shown that the presence of the wall causes the quadrotor UAV to pitch down, essentially flipping it into the wall.

\textsuperscript{1}This work is partially funded by the FRQNT BIX Scholarship

5:58PM B17.00007 Multi-rotor Unmanned Aerial Vehicle (UAV) performance under shear flow\textsuperscript{1}, NINGSHEAN WANG, ALEKSANDAR DZODIC, DOM DIDOMINIC III, AMIT SANYAL, MARK GLAUSER, Syracuse University — Several multi-rotor UAV test flights under shear flow turbulence are carried out. This research targets evaluating the flight performance of the multi-rotor UAV when exposed to shear flow. The UAV deployed with different types of control schemes is exposed to shear flow with different shear rates and freestream velocities to gain its performance under a variety of conditions. Characterization of the shear flow field is evaluated by an array of total pressure scanners to measure the shear rate and free stream velocity spatially. The flight performance data is achieved through the Inertial Measurement Unit (IMU) integrated inside the UAV controller.

\textsuperscript{1}The authors are grateful to the support from Syracuse University and Dr. Mark Glauser for this research.
behavior of alignments are unaffected by the grid-rotation protocols and the modest transverse inhomogeneity. We also find that the local vorticity vector aligns with the large-scale vortical structures being stretched and aligned with the mean strain rate. The results show that the flow characteristics of the circular cylinder strongly depends on the Reynolds number. As the Re increases, this size and shape of wake structures become smaller and narrower with the dramatic reduction of the drag. This is due to the one and two bubble transition leading to the reattachment and delay of separation point. Although the general flow and load characteristics of the circular cylinder are well documented in the literature, it is still hard to find the detailed information of flow fields and local pressure distributions on the circular cylinder, especially at the supercritical Reynolds number. Therefore, this study will be able to provide meaningful information to improve our understanding of the physical insight into the relationship between the loads and wake structures. Moreover, this will contribute to the validation of CFD codes.

This research was supported by a grant from Endowment Project of Research of Turbulent Flow around Circular Cylinder using 3D PIV and Comparative Study of Turbulent Modeling funded by Korea Research Institute of Ships and Ocean engineering (PES 3320).

Measurement of flow fields and local pressures on a circular cylinder at the Reynolds numbers up to $10^6$. JAE HWAN JUNG, SEOKKYU CHO, Korea Res Inst of Ships and Ocean Eng (KRIOS), HYUNWOO JUNG, Seoul Natl Univ, JUN-HEE LEE, YONG-GUK LEE, HONG GUN SUNG, BU-GEUN PAIK, Korea Res Inst of Ships and Ocean Eng (KRIOS) — The present study is aimed to measure the turbulent flow fields and local pressures on a circular cylinder at the Reynolds numbers up to $10^6$. Unlike the previous studies mainly focused on the subcritical flow regime, the supercritical flow regime, which is more realistic to the full-scale condition of engineering, is considered in the present study. The particle image velocimetry (PIV) and local pressure scanner systems are employed to measure local mean pressures and flow fields on the circular cylinder. The results show that the flow characteristics of the circular cylinder strongly depends on the Reynolds number. As the Re increases, this size and shape of wake structures become smaller and narrower with the dramatic reduction of the drag. This is due to the one and two bubble transition leading to the reattachment and delay of separation point. Although the general flow and load characteristics of the circular cylinder are well documented in the literature, it is still hard to find the detailed information of flow fields and local pressure distributions on the circular cylinder, especially at the supercritical Reynolds number. Therefore, this study will be able to provide meaningful information to improve our understanding of the physical insight into the relationship between the loads and wake structures. Moreover, this will contribute to the validation of CFD codes.

5:06 PM B18.00003 Turbulent characterization generated by an active grid in a circular geometry. LOC DUFFO, R. JASON HEARST, Norwegian University of Science and Technology, THIERRY SCHULLER, Institut de Mcanique des Fluides de Toulouse, JAMES R. DAWSON, Norwegian University of Science and Technology — Experimentally inducing turbulence is of importance in understanding many practical flows. Recently active grids have been used to control the turbulence intensity and the integral length scale. However, these studies are almost exclusively based on diamond grids inserted in a square section. The aim of the current study is to design and test an active grid suitable for small diameter circular sections, with the ultimate goal of controlling inlet conditions for reacting flows. The characterization of the turbulence created by the circular sector paddles include various parameters such as paddle rotations speeds, number and shapes of paddles and number of active grid stages. These parameters were tested and compared in order to find the most efficient way to obtain a high level of turbulence intensity while retaining homogeneity. High turbulence intensities in the range of 10 to 20% were achieved using the circular geometry, which was comparable to that of previous square geometry studies. These experiments and results will enable the study of high intensity turbulence in circular geometry.

5:19 PM B18.00004 Influence of Atmospheric Flow Conditions on Scalar-mediated Mosquito Behavior. YI-CHUN HUANG, Princeton University, NEIL VICKERS, University of Utah, MARCUS HALTMARK, Princeton University — Mosquito-vectored diseases are increasingly problematic around the globe where they pose a current and emerging threat to public health. Female mosquitoes locate potential hosts by tracking CO2, volatile skin emanations, humidity, and thermal cues, each of which act as passive scalars that are distributed by local flow conditions. In a preliminary study, 3D field measurements of wind conditions and simultaneous mosquito captures in CO2-baited traps have shown that flight activity occurs during turbulent conditions. However, using field data, it is impossible to uncouple turbulent statistics from each other and from the mean wind speed. To fully explore the parameter space, a unique active flow modulation grid of independently operated paddles was developed. Unlike static grids that generate turbulence within a predefined range of scales, an active grid imposes variable and controllable turbulent structures onto the moving air by synchronized rotation of the paddles at specified frequencies. In the long-term, by leveraging such technology, host-seeking orientation strategies of these insects can be studied and the efficacy of traditional or new approaches that target the behavioral responses of mosquitoes can be rigorously assessed.

5:32 PM B18.00005 Turbulence scaling in the heliosheath and in the local interstellar medium from Voyager observations. FEDERICO FRATERNELLE, Politecnico di Torino, NIKOLAIV. POLOGORELOV, University of Alabama in Huntsville, JOHN D. RICHARDSON, MIT, DANIELA TORDELLA, Politecnico di Torino — This study considers the recent observations of magnetic field fluctuations in the inner heliosheath (IHS) and in the Local Interstellar Medium (LISM). We analyze in-situ data provided by the Voyager In- terstellar Mission (V1 and V2 spacecraft) for heliocentric distances up to 115 AU (V2) and 135 AU (V1). Turbulence, instabilities and recon- nection near the heliopause affect the particle transport and magnetic energy conversion into kinetic energy and into heat. A relevant medi-ation effect on plasma fluctuations is expected from charge exchange processes, which extensively generate pickup ions and energetic neu- tral atoms. We discuss the multi-scale features of magnetic fluctuations for a six-decades range of spacecraft-frame frequencies, which includes the energy-injection regime, the inertial cascade and the fluid-to-kinetic transition. In the IHS, our study reveals the presence of two relevant scales within the magnetohydrodynamic regime, and highlights a cor- relation between the intermittency and compressibility of fluctuations. In the LISM, we show that the dominant Alfvnic character observed in 2015/2016 is not retained during 2017, when the large-scale compressibility reaches the value of 0.6.
fluctuations in warm cloud and clear air environments. A Lagrangian set of data can then be obtained by fusion of GPS (Global Positioning System) and IMU (Inertial Measurement Unit) sensor output. GPS and IMU data can be integrated using the Kalman filter, where GPS provides the periodic updates for removing drifts in the IMU output. This data set can be of help in developing stochastic models to account for turbulence effects on cloud formation.

Session B19 CFD: Advanced Methods and Models 1

4:40PM B19.00001 In situ data compression for large-scale computational fluid dynamics simulations via interpolative decomposition methods1, HEATHER PACELLA, Stanford University, ALEC DUNTON, ALIREZA DOOSTAN, University of Colorado, Boulder, GIANNI ELIAC, Stanford University — Over the next decade, exascale supercomputers will provide a thousand-fold increase in floating-point performance, with memory increase of only a factor of one hundred. As a result, data generation from computational fluid dynamics simulations will easily surpass available memory capacity. Additional data compression techniques and optimization will also contribute to this discrepancy. To address this, we implement a lossy in situ compressive algorithm, interpolative decomposition (ID), within the solvers themselves, which allows us to store simulation results at a fraction of memory cost. Because ID algorithms operate independently on subregions of the fluid domain, they are a natural fit for the flexibility that task-based parallelism programming systems provide. Legion is one such programming system; it allows for implicitly extracted parallelism, easy performance tuning, and porting to various heterogeneous architectures. We will discuss the implementation of the interpolation and optimization within Legion, as well as performance, scalability, and cost of both ID algorithms in a task-parallel environment.

5:06PM B19.00003 Modeling the Effect of Resolution Inhomogeneity in LES, GOPAL YALLA, ROBERT MOSER, TODD OLIVER, Oden Institute for Computational Engineering and Sciences, The University of Texas at Austin, SIGFRIED HAERING, Argonne National Laboratory, BJORNE ENQUIST, Oden Institute for Computational Engineering and Sciences, The University of Texas at Austin — In LES, the unresolved turbulent stress is split into a mean and fluctuating portion, each with their own model. The AMS has shown improved accuracy in keeping computational cost low. Nevertheless, their predictive accuracy is limited by shortcomings such as modeled-stress-depletion and scalar grid measures. Haering, Oliver, and Moser developed an “active model-split” (AMS) to address many of these shortcomings. This model splits the unresolved turbulent stress into a mean and fluctuating portion, each with their own model. The AMS has shown improved accuracy in several incompressible test cases. In order to allow more complex test cases, this new model has been applied to the compressible flow equations and implemented in SU2. Results are presented for several compressible test cases, including supersonic channel and boundary layer flows and the Bachlo and Johnson transonic, axisymmetric bump.

5:32PM B19.00005 Hyperviscosity and bottlenecks in the Taylor-Green vortex, RAHUL AGRAWAL, IIT-Bombay, ALEXANDROS ALEXAKIS, MARC BRACHET, LPS-ENS, LAURETTE TUCKERMAN, PMNH-CNRS-ESPCI-Paris — Direct numerical simulations of turbulence are sometimes performed with hyperviscosity, in which the standard viscous term is replaced by a higher power \( p \) of the Laplacian, in order to increase the dissipation at high wavenumbers and thus to widen the computationally accessible inertial range. It is essential to determine the effect of hyperviscosity on various features of the turbulent energy spectrum, such as the bottleneck, an increase in energy for wavenumbers just below the dissipation range. Here, we use the symmetries of decaying Taylor-Green flow to study the effect of hyperviscosity on the bottleneck in high-resolution direct numerical simulations for resolutions up to \( 1024^3 \) and for hyperviscosity up to order \( p = 100 \), using simulations with \( 2048^3 \) and \( p = 1 \) as a reference case. We also investigate numerical issues that must be addressed for these high parameter values, in particular the timestepping scheme, the timestep, and the evaluation of the dissipation.

We investigate an anisotropy-resolving subgrid-scale (SGS) model for large eddy simulation, which is constructed by combining an isotropic linear eddy-viscosity model (EVM) with an extra anisotropic term (EAT) (Abe, Int. J. Heat Fluid Flow, 39, pp. 42-52 (2013)). In this study, to reveal the role of the EAT in the SGS model, we performed simulations using several combinations for the terms involved in the SGS model, e.g., only EVM, only EAT as well as full version (EVM+EAT). We calculate the power spectrum of the GS velocity component from the obtained data and then compared them in detail. The comparison shows that the EAT works well for enhancing small-scale structures, resulting in an apparent upshift of the power spectrum particularly in a high-wavenumber region. We further investigate another option for the EAT instead of the currently-used formulation, e.g., a modified Leonard-stress formulation.

Asynchronous Direct Numerical Simulations (DNS) of turbulent flows at extreme scales. KOMAL KUMARI, DIEGO DONZIS, Texas A&M University — A major challenge in turbulence simulations is to accurately resolve the wide range of spatio-temporal scales. The computational cost of well resolved DNS grows with Reynolds number steeply and therefore, necessitates the use of massively parallel computations on supercomputers. However, the increase in communication and synchronization cost of current approaches could pose an insurmountable bottleneck at extreme scales. Thus, we have developed a novel paradigm, which relaxes these synchronization requirements at a mathematical level and leads to the so-called Asynchrony-Tolerant (AT) schemes. A first of its kind implementation of these schemes in a 3-D compressible Navier-Stokes DNS solver (forced and decaying) will be presented. Implementation of asynchrony using communication and synchronization avoiding algorithms resulting in periodic and random delays will be discussed. We show that these asynchronous algorithms accurately resolve large and small scale characteristics of turbulence, including instantaneous fields. We also show their efficiency in mitigating the communication bottleneck. The improved scaling, without affecting the physics, makes this asynchronous paradigm a path towards exascale simulations of turbulence and other non-linear phenomena.

A laboratory study of gas giants' zonal jets: formation and long-term evolution. DAPHNE LEMASQUERIER, BENJAMIN FAVIER, MICHAEL LE BARS, Aix-Marseille Univ, CNRS, Centrale Marseille, I.R.P.H.E, UMR 7342, 49 rue F. Joliot Curie, 13013 Marseille — The stability, structure and dynamics of gas giants' zonal jet streams are still poorly understood, especially in terms of coupling with their deep molecular interior. Here, we use an experimental approach to address the questions of zonal jets formation and long-term evolution. A strong topographic β-effect is obtained inside a rotating water tank thanks to the paraboloidal shape of the fluid free surface due the centrifugally-induced pressure. The shape of the bottom of the tank is chosen so that this β-effect is spatially constant. A small-scale turbulent forcing is performed over 128 injection and suction points at the base of the tank allowing a control of its spatio-temporal distribution and intensity. Time-resolving PIV measurements are performed in a horizontal plane. We identify a subcritical bifurcation between two regimes where zonal jets with strong instantaneous signature are present. In the first regime, the jets are weak in amplitude, directly forced and steady. In the second one, we observe self-developed highly energetic jets, independent of the forcing scale. In that last case, the zonal flows kinetic energy spectra are consistent with theoretical predictions in the regime of so-called zonostrophic turbulence relevant to planetary applications.

Shelf flow crossing over a strait: Experimental. JOSEPH KUEHL, University of Delaware, VITALII SHEREMET, NOAA — Motivated by the phenomenon of Scotian Shelf Crossover events (Bisagni et al. 1998), a problem of a shelf flow that is interrupted by a strait is considered. Laboratory experiments in a rotating tank with barotropic and baroclinic flow over flat and sloping shelves confirms that the flow is steered by the bathymetric contours and mainly circumnavigates the gulf. In order to jump across the strait, as suggested by earlier theories, the flow must have unrealistically high Rossby numbers. However, the near bottom friction relaxes the bathymetric constraint (Kuehl 2014) and causes the formation of a peculiar jet crossing the strait diagonally. Numerical solutions for realistic values of the frictional parameter reproduce the results of the laboratory experiments and are similar to the patterns observed in the satellite derived sea surface temperature fields (Smith 1983). Bisagni, J. J., R. C. Beardsley, C. M. Rusham, J. P. Manning, and W. Williams, 1996. Deep-Sea Research, 43, 1439-1471. Kuehl, J. J., 2014. Geophysical Research Letters, 41. Smith, P. C., 1983. Direct Statistical Simulations of a Rotating Thermal Annulus. JEF-FREY OISHI, Bates College, STEVEN TOBIAS, University of Leeds, BRAD MARSTON, Brown University, KEATON BURNS, Massachusetts Institute of Technology — Turbulent systems generate and interact with mean flows in a wide variety of natural systems. Understanding the nature of these interactions, particularly for systems far from equilibrium, remains a paramount priority in understanding large-scale flows on planets and stars. The fundamental problem in studying such systems via direct numerical simulation (DNS) is the fact that the smallest scales can have a significant impact on the mean flows, even when they are very widely separated. One way to make progress is to study the statistics of the flow rather than detailed flow variables themselves. By expanding around the mean flow in terms of equal-time cumulants, we can arrive at a closed set of equations of motion for the cumulants. Here, we present results using an expansion terminated at the second cumulant (CE2) for rapidly rotating thermal convection in an annulus. CE2 discards eddy-eddy interactions that yield eddies; it is fundamentally quasi-linear. We focus on a particular case in which the direct numerical simulation yields an initial three-jet solution that is unstable to a two-jet solution. Interestingly, CE2 predicts a stable three-jet solution, though we find that by biasing the initial conditions to favor certain symmetries, CE2 reproduces the DNS results.
5:32PM B20.00005 Mixing in Steady-State Gravity Currents, JIM MCELWAIN, Durham University; CLAUDIA CENEDESE, Woods Hole Oceanographic Institution, JEFFREY HENINGER, U. Texas at Austin — Turbulence currents have been observed to propagate for very long distances, longer than one would expect based on the current knowledge of mixing and evolution of gravity currents. Recent DNS simulations suggest that when in steady state the gravity current presents a much more stable interface, potentially reducing the mixing with ambient waters and hence being able to survive and propagate for longer distances. We report experiments that investigate experimentally 'steady state' gravity currents as opposed to lock-release gravity currents, with particular emphasis on the interfacial instability and assess whether the 'flavor' characteristics of this shear instability and the induced turbulence are different in steady state scenario as opposed to a more 'transient' scenario which has been investigated using lock-release gravity currents. We report on gravity current experiments in a flume that have reached a statistically steady state and compare the results to those obtained with a classic lock release set up, DNS and theoretical results.

5:45PM B20.00006 Effect of Inertial Migration of Particles on Flow Transitions of a Suspension in Taylor–Couette Geometry, LINA BAROUDI, ALEXANDER LIGAY, Manhattan College, MADHU MAJJI, University of California, Santa Barbara, JEFFREY MORRIS, CUNY City College of New York — This study presents an experimental investigation into the influence of inertial migration of neutrally buoyant non-Brownian particles on inertial flow transitions of a suspension in Taylor–Couette geometry. A concentric cylinder Taylor-Couette device with a stationary outer cylinder and rotating inner cylinder is considered. The device has an inner to outer radius ratio of 0.1. Starting with the circular Couette flow (CCF) regime with inertially migrated concentration profile in this regime, a lower onset Reynolds number observed when starting with uniform suspension concentration. For inertially migrated concentration profile in CCF, the non-axisymmetric flow states between CCF and Taylor vortex flow (TVF) reported by Majji et al. (JFM 835, 936 (2018)) were also observed here but at lower compared to uniform suspension concentrations. On contrary to the stabilizing effect obtained from the linear stability analysis of CCF with varying viscosity profile in the annular region, our results reveal a destabilizing effect to the CCF due to the inertially migrated concentration profiles.

5:58PM B20.00007 Vorticity shedding from a sphere moving vertically in a stratified fluid, HIDESHII HANAZAKI, TATSUYA YASUDA, KOKI TAKAGI, SHINYA OKINO, Kyoto University — A numerical study is described of the flow past a sphere moving at constant speeds in a stratified fluid. The wake under moderate or strong stratification remains axisymmetric even for $Re > 200$, unlike the flow of a homogeneous fluid which becomes asymmetric for $Re > 200$. A striking feature is that this axisymmetric flow often gives, under moderate stratification, an axisymmetric 'vorticity' shedding, which has never been observed in the wake of an axisymmetric bluff body. In this study, corresponding experiments have also been performed, showing that a non-axisymmetric wake with horizontal fluctuations tend to appear at some heights above the sphere. This suggests that the axisymmetric flow would be hard to be realised in actual flows at high Reynolds numbers ($Re > 200$).

Saturday, November 23, 2019 4:40PM - 6:11PM – Session B21 Drops: Temperature and Marangoni Effects II 603 - Kirti Sahu, Indian Institute of Technology Hyderabad India

4:40PM B21.00001 Drop impact on heated nanostructures, LIHUI LIU, University of Alberta; Beihang University, GUOBIAO CAI, Beihang University, PEICHUN AMY TSAI, University of Alberta — Drop impact on a heated surface not only displays fascinating dynamics but also plays a crucial role in many industrial processes, such as spray cooling, metallurgy, and fuel injection. We experimentally investigate the impact dynamics of water droplets on both polished and nanostructured heated silica surfaces, under a wide range of surface temperature and impact speed (i.e., Weber number). For the polished surface, at a low surface temperature (below 200°C) water drop gently spread on the surface. Whereas, at a higher temperature (above the Leidenfrost point) the droplets completely rebound, with accompanying boiling, atomizing, and eventually splash as the Weber number increases. We show that the nano-structures significantly affect the impact dynamics, compared to that on the polished surface. In particular, the nano-textures can easily prompt splashing, vapor bursting, and jetting. We also found that the surface roughness and packing fraction of the nano-structures influence the impact outcomes.

4:53PM B21.00002 Marangoni spreading and contracting three-component droplets on completely wetting surfaces, NATE CIRA, DIETER BAUMGARTNER, SHAYANDEV SINHA, Rowland Institute at Harvard University, STEFAN KARPITSCHKA, Max-Planck Institute for Dynamics and Self-organization — Marangoni flows are a well-established mechanism for inducing droplet spreading and contraction. In this work, we study the behavior of a three-component mixture (ethanol, water, and propylene glycol) on high energy surfaces. Evaporation driven concentration differences give rise to surface tension gradients and Marangoni flows responsible for three categories of behavior across the ternary concentration space – contraction, enhanced spreading, and sequential spreading then contraction. Based on the combined effects of each component’s evaporation on surface tension, we predict boundaries for each of these behaviors that align well with experimental data across a wide range of concentrations and humidities. We present additional data on how internal flow structures impact droplet shape. Self-expansion and contraction make these droplets suitable for cleaning high energy surfaces.

5:06PM B21.00003 Solutal Marangoni Flows in Premixed Alcohol-water Solution, HYOUNGSOO KIM, KAIST, HAN SEO KO, Sungkyunkwan University — To date, the origin of solutal Marangoni flows in a premixed alcohol-water solution has not been investigated although the solutal Marangoni effects are widely used for various applications including material migration, mixing, coating and cleaning. It is reported that there is a flow transition during the evaporation of the premixed alcohol-water solution. Not from the pre-mixed alcohol-water mixture, we also show that the multiple irregular vortices in an evaporating water droplet were created where the cloud of alcohol molecules in the air covered the droplet, which induces a local surface tension variation. Interestingly, the flow pattern is also very similar to the case of the premixed water-alcohol solution droplet. By comparing these two different cases, we tried to explain how the solutal Marangoni flow occurs in the alcohol-water mixture solution.

Bouncing behaviors of an oil droplet in a stratified liquid

ZELAI XU, JUNYUAN CHEN, HAORAN LIU, HANG DING, University of Science and Technology of China

A liquid desiccant is a hygroscopic aqueous solution widely used in dehumidification processes. In this study, the temperature gradient affects the wetted length of the drop. The wetted length obeys an exponential function with time, but it diverges at the later stage due to the increase in the drop deformation. On the other hand, in the stretching regime, the drop continues to spread about its initial location as it experiences a higher surface tension force on the substrate. In contrast, in the displacement regime, the drop spreads slightly and moves towards one side of the substrate. In this regime, the drop experiences a lower apparent contact angle, opposing the prediction from evaporation-driven stabilization alone. Paired data from visualizing internal flow patterns for various liquids and substrates show that these effects on angle are consistent with observed Marangoni flows. These results underscore the importance of considering Marangoni flow in understanding the shape of evaporating highly volatile droplets on fully wetting surfaces.

Marangoni flow influences apparent contact angle of single component volatile liquids on completely wetting surfaces

SHAYANDEV SINHA, Rowland Institute at Harvard, Harvard University

Dhuynevolatile single-component liquids on completely wetting surfaces, we observe two scaling laws, with the wetted length of the drop increasing with time, $t$. The present work provides information on the physics of the interaction of droplets with a free surface and presents a new methodology for modeling triple contact lines. This method can be used in a wide range of applications involving three immiscible liquids.

Marangoni flow influences apparent contact angle of single component volatile liquids on completely wetting surfaces

ZHENYING WANG, Kyushu University, GEORGE KARAPETSAS, Aristotle University of Thessaloniki, PRASHANT VALLURI, ADAM WILLIAMS, University of Edinburgh, KHELLIL SEFIANE, Kyushu University; University of Edinburgh, YANSHEN LI, CHRISTIAN DIDDENS, LIJUN THAYIL RAJU, University of Twente, XUEHUA ZHANG, University of Alberta, KAI LEONG CHONG, University of Twente, ANDREA PROSPERETTI, University of Houston, DETLEF LOHSE, University of Twente — As we had found in Li et al. (2019), an oil droplet is able to repeatedly first sink and then bounce up in a vertically stratified ethanol-water mixture. The Marangoni flow at the droplet-liquid interface, caused by the solute (ethanol) gradient, provides the propulsion for the upwards jump. We now further elucidate the mechanism and explore the phase space. Specifically, we find that as the droplet jumps up to the lighter ethanol-rich region, it gets harder for the propelling droplet to overcome its own weight, until finally it stops. At this maximum height, the Marangoni flow continues to propel, homogenizing its surrounding liquid, thus decreasing the propulsion itself, until it ceases. The droplet then sinks while dragging down this uniform liquid layer with it. We find that this uniform “shielding” layer eventually vanishes, mainly because of diffusion, so that the droplet bounces up again, continuing the cycle. It is also found that the maximum height increases with decreasing the droplet size.

We thank the Rowland Fellow program for funding this work.

Motion of self-rewetting drop on a substrate with a linear temperature gradient

ZELAI XU, JUNYUAN CHEN, HAORAN LIU, HANG DING, University of Science and Technology of China

The present work provides information on the physics of the interaction of droplets with a free surface and presents a new methodology for modeling triple contact lines. This method can be used in a wide range of applications involving three immiscible liquids.

Lubrication model for vapor absorption into hygroscopic liquid desiccant droplets

ZHENYING WANG, Kyushu University, GEORGE KARAPETSAS, Aristotle University of Thessaloniki, PRASHANT VALLURI, ADAM WILLIAMS, University of Edinburgh, KHELLIL SEFIANE, Kyushu University; University of Edinburgh, YANSHEN LI, CHRISTIAN DIDDENS, LIJUN THAYIL RAJU, University of Twente, XUEHUA ZHANG, University of Alberta, KAI LEONG CHONG, University of Twente, ANDREA PROSPERETTI, University of Houston, DETLEF LOHSE, University of Twente — As we had found in Li et al. (2019), an oil droplet is able to repeatedly first sink and then bounce up in a vertically stratified ethanol-water mixture. The Marangoni flow at the droplet-liquid interface, caused by the solute (ethanol) gradient, provides the propulsion for the upwards jump. We now further elucidate the mechanism and explore the phase space. Specifically, we find that as the droplet jumps up to the lighter ethanol-rich region, it gets harder for the propelling droplet to overcome its own weight, until finally it stops. At this maximum height, the Marangoni flow continues to propel, homogenizing its surrounding liquid, thus decreasing the propulsion itself, until it ceases. The droplet then sinks while dragging down this uniform liquid layer with it. We find that this uniform “shielding” layer eventually vanishes, mainly because of diffusion, so that the droplet bounces up again, continuing the cycle. It is also found that the maximum height increases with decreasing the droplet size.

4:53PM B22.00002 Partial coalescence of a droplet with a pool of different viscosity\(^1\).

ABDULLAH AL ALHARETH, SIGURDUR T. THORODDSEN, King Abdullah University of Science and Technology — The partial coalescence of a droplet with a liquid surface is a critical factor during the coarsening of emulsions, as this process can produce smaller droplets. It is well-known that increased liquid viscosity or reduced drop size will eventually stop the satellite pinch-off at a critical Ohnesorge number. On the other hand, similar satellites can be pinched off during the rapid spreading of a drop on a solid surface, if it is strongly hydrophilic. Herein we study this process when the substrate transitions from low to high viscosity liquid, modeled to approach the boundary conditions of a solid. We use miscible silicone oils, with a low-viscosity drop and a large range of pool viscosities up to a million times that of the drop. We observe non-monotonic behavior and as the viscosity increases we see a propensity for second-stage pinch-off. We connect the observed critical Ohnesorge numbers to the spreading behavior. 1. Zhang, Li & Thoroddsen, Phys. Rev. Lett. 102,104502 (2009).

\(^1\)This work was funded by King Abdullah University of Science and Technology (KAUST) under Grant No. URF/1/2621-01-01.

SWATI SINGH, ARUN K. SAHA, Indian Institute of Technology Kanpur, Kanpur, India — The drop coalescence is important in many applications such as formation of rain drops in cloud and mixing in microdevices. In the present work, the dynamics of satellite drop generation during the coalescence of two drops of unequal size are studied. The mechanism depends on five non-dimensional parameters: Ohnesorge number for both liquids, Bond number, Atwood number and the diameter ratio of two drops. We have performed two-dimensional, axisymmetric simulations using Coupled Level set and Volume of fluid method (CLSVOF) to unveil the underlying physics of coalescence process under varying drop diameter ratio (1.0-9.0) and Ohnesorge number. The Bond number is kept less than 0.1. Result shows the three different pinch-off scenario depending on drop diameter ratio: (i) the mother drop deforms after coalescence resulting in necking and subsequent satellite drop pinches off following the similar sequence as that of a drop coalescence with a flat liquid pool, (ii) occurrence of mother drop pinch-off happens with necking but without intermediate detachment of satellite drop, (iii) mother drop completely coalesces into the father drop without any evidence of satellite drop generation.

5:19PM B22.00004 Two Fluid Coalescence of Drops in an Exterior Fluid.

CHRISTOPHER ANTHONY, MICHAEL HARRIS, OSMAN BASARAN, Purdue University — The coalescence of drops and bubbles has been investigated in numerous experimental, numerical and theoretical studies due to its prevalence in industrial and natural processes. In many studies to date, either the interior/dispersed phase (e.g. the gas inside bubbles) or the exterior/continuous phase (e.g. the air surrounding drops) has been treated as dynamically inert in order to simplify the analysis. However, in many systems of interest, the interior and the exterior phases are fluids of comparable viscosities and/or densities, and treating one as dynamically inert may be inappropriate. Indeed, theoretical arguments by Eggers et al. suggest that the interior fluid will always play a role at some early time but that this could occur at length scales below the continuum limit (e.g. with bubbles). To date, the scaling behavior predicted by Eggers et al. for viscous drops in a viscous medium has been contradicted by experimental observations and no numerical study has been able to resolve this contradiction. Here, we explore through high fidelity numerical simulations drop coalescence in an exterior medium paying particular attention to the high viscosity or creeping flow limit while also considering a limited number of cases of finite viscosity.

5:32PM B22.00005 Non-continuum tangential resistivity functions for two spheres suspended in a gas\(^1\), MELANIE LI SING HOW, DONALD L. KOCH, LANCE R. COLLINS, Cornell University — In the limit of absence of gas-phase inertia, the motion of two spheres is described by the Stokes equation for large separations and by the linearized Boltzmann equation for separations comparable with the mean-free path of the gas. The forces and torques the gas exerts on each sphere are described by five resistivity functions (Jeffrey & Onishi, J. Fluid Mech. 139: 261-290 1984). The resistivity functions undergo a transition as the separation distance between the spheres approaches the mean free path of the gas. In particular, the divergences of the Stokes resistivity functions as the spheres approach contact are reduced by non-continuum effects. We present modified tangential resistivity functions that are uniformly valid through this transition (i.e., from the continuum limit at distant separations to separations where the lubrication flow near contact is a free molecular flow). We apply the modified resistivity functions to two illuminating cases: (i) a sphere falling in close proximity to a vertical wall; and (ii) two spheres settling under gravity. The results show qualitative differences from the classical Stokes flow solution and are applied to the study of coalescing cloud droplets settling under gravity.

\(^1\)CBET - 1605195

5:45PM B22.00006 Coalescence dynamics of two unequal size water droplets in air.

NITIN GOYAL, ATUL SHARMA, Indian Institute of Technology Bombay — Coalescence dynamics of two water droplets falling under gravity in air, is studied for various diameter ratio \(d_{\text{bottom}}/d_{\text{top}}\). \(D_r = 0.156-0.4\) and Ohnesorge number \(Oh = 0.001-0.025\) at a Bond number \(Bo = 0.092\). Axisymmetric simulations are done using sharp interface level set method based in-house code. We presented a regime map for the various \(Oh\) and \(D_r\), with partial coalescence at smaller as well as larger values of \(D_r\) and full coalescence at intermediate value of \(D_r\). For a transition in the coalescence dynamics, the present work reports a smaller and a larger critical value of \(D_r\) as compared to one critical \(D_r\) (the larger one) reported in the literature. Over the range of \(Oh\) studied here, there is a monotonic increase in both the critical \(D_r\) with increasing \(Oh\) from 1.5 to 5.7 for the larger critical \(D_r\) and from 0.3 to 0.4 for the smaller critical \(D_r\). The pinch-off height of satellite droplet is larger for partial coalescence at the larger \(D_r\) as compared to that at the smaller \(D_r\). The partial coalescence regime at the smaller \(D_r\) is presented here for the first time.

Saturday, November 23, 2019 4:40PM - 6:11PM — Session B23: Drops: Electric Field Effects I

4:40PM B23.00001 Electrohydrodynamic Equatorial Streaming

BRAYDEN WAGONER, CHRISTOPHER ANTHONY, Purdue University, PETIA VLAVHOVSKA, Northwestern University, MICHAEL HARRIS, OSMAN BASARAN, Purdue University, SCHOOL OF CHEMICAL ENGINEERING, PURDUE UNIVERSITY TEAM, ENGINEERING SCIENCES AND APPLIED MATHEMATICS, NORTHWESTERN UNIVERSITY TEAM — When subjected to electric fields, spherical liquid drops can deform, and disintegrate by fissioning, cone-jetting, and in a variety of other ways. The strength of the electric field as well as the electrical and other physical properties of the drop and surrounding medium determine both the extent and type of deformation (prolate/oblate) that the drops can undergo prior to disintegration. At large electric field strengths, prolate drops emit thin jets from conical structures (Taylor cones) that form at their poles. Oblate drops, on the other hand, may burst at their centers (dimpling) or emit a thin sheet from their equators (equatorial-streaming) [Brossoue and Vlahovska, Phys. Rev. Lett., vol. 119, 2017]. We probe the physics behind these two oblate instabilities through direct numerical simulation.
Numerical simulations on the extended lubrication theory is developed in order to predict the bubble velocity and steady state solutions of the film profiles in different directions. By varying the capillary number of the external downward flow, different film profile regimes are observed. A theoretical model based on electrowetting can be used as a macroscopic probe into the structure of the EDL. Not all drops of commercial hydrogel, agar-agar, alginate, xanthan gum, and gum Arabic can be moved by electrowetting. Drops of sizes of 200 \textmu{}m and several aqueous polymer solutions, like those of polyethylene oxide and polyacrylamide result in drop motions similar to that of water drops. Several aqueous polymer solutions, like those of polyethylene oxide and polyacrylamide result in drop motions similar to that of water drops. The spreading time to reach this final state varies as \( c_0^{-1} \) and the receding time varies as \( c_0^{-1/2} \). We show that both spreading and receding times are governed by the formation of the electrical double layer (EDL) on the substrate, and that electrowetting can be used as a macroscopic probe into the structure of the EDL.

Ambient Air Humidity Affects the Charge Acquired by Water Drops in Oil. By varying the capillary number of the external downward flow, different film profile regimes are observed. A theoretical model based on electrowetting can be used as a macroscopic probe into the structure of the EDL.

Dynamics of electrowetting-driven spreading and receding of a droplet. By studying the effect of electrolyte concentration on electrowetting-induced spreading and receding of a droplet on the basal plane of graphite, a smooth conducting substrate. We find that for positive applied potentials, the static electrowetting contact angle contact angle is independent of \( c_0 \) over three decades of concentration but that the spreading time to reach this final state varies as \( c_0^{-1} \). In contrast, for negative potentials, the electrowetting angle varies as \( 1/c_0 \) and the spreading time varies as \( c_0^{-1/2} \). We show that both spreading and receding times are governed by the formation of the electrical double layer (EDL) on the substrate, and that electrowetting can be used as a macroscopic probe into the structure of the EDL.

Drop Manipulation by Electrowetting for 3D Printing. Drops of commercial hydrogel, agar-agar, alginate, xanthan gum, and gum Arabic can be moved by electrowetting. Drops of sizes of 200 \textmu{}m and 3 mm can be manipulated by the electric field on different dielectric substrates accurately and repeatedly. This includes horizontal motions, motions on vertical wall, and upside down. Theoretical aspects are discussed as well.

Rising or Sinking — An Elongated Bubble in a Vertical Capillary Tube Under External Flow. When a confined bubble translates steadily in a vertical capillary tube under co-current fluid flow, the motion of the bubble depends on both the buoyancy and the mean fluid velocity. Although a wide variety of studies have been carried out analyzing the motion of the elongated confined bubble, most of them focus on the dynamics in one of two distinct limit — either when buoyancy effects are negligible (\( Bo << 1 \)) or when \( Bo >> 1 \). This work, we systematically investigate the motion of an elongated bubble and its film thickness profile with \( Bo = 1 \) under external downward flow. In a stagnant fluid, a bubble spontaneously rises only when \( Bo > 0.842 \) (Bretherton 1961), and intuitively, external downward flow can slow down the bubble motion or even reverse the translation direction. By varying the capillary number of the external downward flow, different film profile regimes are observed. A theoretical model based on the extended lubrication theory is developed in order to predict the bubble velocity and steady state solutions of the film profiles in different regimes. The critical external flow conditions are further characterized and validated by combining with the results from experiments and direct numerical simulations.

4:53PM B24.00002 Effect of wake behind a rising bubble on the heat transfer of the vertical heated wall\(^1\)  Hwiyoung Maeng, Hyungmin Park, Seoul National University — We conduct experiments with two kind of bubbles (linear and zigzagging bubble of which Reynolds number is 200 and 850) rising near the vertical heated (at a constant heat flux of 2000 W/m\(^2\)) wall. While varying the distance between the bubble and the wall, we measure the gas- and liquid-phase flow fields with two-phase PIV and wall temperature distribution using an infrared camera simultaneously. We find out that the wake emanating behind the zigzag bubble convects laterally toward the wall, disturbing the natural convective boundary layer and enhances the local convective heat transfer, which is quantified as a Nusselt number (Nu) normalized by that of natural convection. As the distance between the bubble and the wall is smaller, the increasing slope and affected area of the heat transfer become larger. The maximum Nu augmentation is eight times larger than the reference value when the bubble-wall distance is short enough for the bubble to collide with the wall, but the affected area is maximum when the bubble does not collide but passes closely to the wall. In the case of linearly rising bubble, however, the heat transfer enhancement was not measured evidently, because the wake is stationary and does not convect to the vertical wall effectively.

\(^1\)Supported by grants (2017R1A4A1015523, 2017M2A8A4018482, KCG-01-2017-02) funded by Korea government and Korea Coast Guard.

5:06PM B24.00003 Numerical study on the interaction of two bubbles rising in a power-law fluid  Shu Takagi, Varun Jadon, The University of Tokyo, Kazuyasu Sugiyama, Osaka University — In this study, interactions of two bubble rising in a Non-Newtonian power-law fluid have been investigated through the direct numerical simulations. An interface capturing method with a continuous function is introduced and the three-dimensional model based on modified VOF method is used to study two-bubble interaction phenomena in a power-law fluid. Here, we discuss the influence of shear-thinning and shear-thickening characteristics on the interaction of in-line or inclined configurations of two bubbles. The numerical results reveal that the shear-thinning fluid enhances the inviscid potential interaction and in-line motion becomes more unstable in shear-thinning fluid than that in Newtonian Fluid.

5:19PM B24.00004 Effect of viscosity and density ratios on two bubbles rising side-by-side  Sivanandan Kavuri, Mounika Balla, Indian Institute of Technology Hyderabad, India, Manoj Kumar Tripathi, Indian Institute of Science Education and Research Bhopal, Kirti Sahu, Indian Institute of Technology Hyderabad, India, Rama Govindarajan, International Centre for Theoretical Sciences, Bangalore — We study the dynamics of a pair of initially spherical ‘bubbles’ of fluid rising side-by-side in a surrounding, denser, fluid. Interesting dynamics are reported, which cannot be extrapolated from previously known dynamics of gas-liquid systems. Similar to two air bubbles though, we find that two liquid bubbles move away from each other as they rise, in cases where a single bubble would rise vertically. A pair of light bubbles always remains in two-dimensional motion, and higher bubble viscosity increases the tendency of wobbling. This is in contrast with the dynamics of a single bubble that follows a highly three-dimensional trajectory at very low bubble viscosity, but is restricted to two dimensional motion at higher bubble viscosity. On the other hand, a pair of heavier bubbles displays three-dimensional behaviour at low bubble viscosity and two dimensional behaviour at high viscosity. We find that a pair of bubbles is far less sensitive to viscosity contrast than a single bubble is, in our parameter range. In contrast to gas-liquid systems, where shape change of the bubble was tied to nonlinear dynamics of the trajectory, we find in liquid-liquid systems that interesting bubble trajectories can occur without corresponding large shape changes.

5:32PM B24.00005 On the Dynamics of an Oil Encapsulated Bubble  Joel Karp, Ernesto Mancilla, Rigoberito Morales, Federal University of Technology-Parana — The dynamics of an oil encapsulated bubble was experimentally investigated. High-speed imaging was employed in the visualization of the motion of a coated bubble rising in quiescent tap water. The attachment of a bubble with diameter ranging from 300 to 3000 m to a 2.3 mm oil droplet resulted in two different regimes: oscillatory and non-oscillatory motion. The influence of the properties of the oil coating was investigated by employing three different oils, which were found to be more influential when no motion instabilities were observed and viscous forces dominate. Path oscillations decreased for the encapsulated bubble, being up to five times smaller in comparison with an isolated bubble with similar diameter. The oil coated bubble presented higher terminal velocity in comparison to a rising oil droplet, with increase factors from 100 up to 400%. The shape deformation of the encapsulated bubble was less than 15% within the diameter range evaluated, being essentially spherical in comparison to corresponding isolated bubbles. Transient motion assays indicated that developed regime was achieved in approximately half the rising distance than for isolated bubbles, after which a periodic oscillation of the velocity components was observed.

5:45PM B24.00006 Flow boiling in a Horizontal Microchannel with high Aspect Ratio for Non-Uniform (One-Sided) Heating at Different Rotational Orientations\(^1\)  Marius Vermaak, Jaco Dirker, University of Pretoria, Khellil Sefiane, Daniel Orejon, Prashant Valluri, University of Edinburgh, Josua Meyer, University of Pretoria, UNIVERSITY OF PRETORIA TEAM, UNIVERSITY OF EDINBURGH COLLABORATION — Flow boiling of FC72 in a semi-rectangular horizontal microchannel with one-sided heating, was investigated experimentally. Microchannel rotational orientations from bottom-heating (0) to top-heating (180), in 30\(^\circ\) increments were considered. Mass fluxes of 10, 20 and 40 kg/m\(^2\)s, paired with various heat fluxes which spanned from the onset of nucleate boiling to near dry-out conditions, were tested in a borosilicate glass channel of 5x0.5mm internal cross-section. Ohmic resistive heating was obtained via a layer of tantalum oxide that was applied to only one of the outer surfaces of the microchannel. This optically transparent layer allowed for both transient surface temperature mapping and flow visualization. During quasi steady state average and local heat transfer coefficients as well as pressure drop were analyzed. Our results show that bottom-heating produced average heat transfer coefficients at least 17% higher than top-heating. Flow boiling instabilities are promoted at greater wall super-heats, especially in rotations between top-heating and side-heating. The effect of inclination on flow boiling in such microchannels will also be presented.

1 adsorption/absorption) of water in the drop. It has been observed experimentally that in these cases, the ambient relative humidity (RH) and the initial drop composition seems to play a very important role in the wetting dynamics. On varying the composition of IPA/water mixture and alcohol [e.g., Iso-Propanol (IPA)] and water. It has been observed experimentally that in these cases, the ambient relative humidity (RH) and the initial drop composition seems to play a very important role in the wetting dynamics. On varying the composition of IPA/water mixture and RH, with the help of optical interferometry, the droplet spreading behavior has been studied. For better understanding, an analytical model has been developed to characterize the dependence of these parameters on wetting behavior. The model has been conveniently used to generate so-called a map of regime (MOR) diagram which clearly demarcates the different wetting zones depending on the relative evaporation (or adsorption/absorption) of water in the drop.

Saturday, November 23, 2019 4:40PM - 6:11PM – Session B26 Drag Reduction I

4:40PM B26.00001 Active control of deterministic turbulent spots for drag reduction1, KWING-SO CHOI, YAXING WANG, University of Nottingham, MICHAEL GASTER, CHRIS ATKIN, City, University of London, YURY KACHANOY, VLADIMIR BORODULIN, ITAM — A series of experiments was carried out using Gaster’s wind tunnel at City, University of London, where the freestream turbulence level in the test section was extremely low (0.006% between 2 Hz and 2 kHz). With weak excitations applied from spanwise-periodic 19 miniature phasers located downstream of a flat-plate leading edge, the boundary-layer development was studied in detail using a hot-wire anemometer at laminar, transitional and turbulent stages. Careful velocity measurements revealed an appearance of turbulent spots, which were precisely reproducible in both time and space each time the pseudo-random signal was applied. The emergence of turbulent spots, which bypassed a full development of T-S waves, was deterministic at least in the lower frequency range of velocity signals, enabling us to examine their structure that was not possible before. Opposition control was then carried out by issuing wall-normal jet on the high-speed region of turbulent spots with a view to achieve a skin-friction reduction by delaying transition to fully-developed turbulence. This was done without sensors as all boundary-layer structures were “deterministic”.

4:53PM B26.00002 ABSTRACT WITHDRAWN –

5:06PM B26.00003 Active Drag Reduction in Turbulent Airfoil Flow. WOLFGANG SCHRDER, MARIAN ALBERS, Institute of Aerodynamics, RWTH Aachen University — Drag reduction in turbulent boundary layers is key for substantial energy savings in aerodynamics. Large parts of the flow over the wing of modern aircraft are turbulent such that even net energy savings of a few percent lead to high cost savings. Active drag reduction methods have shown to be capable of significantly reducing the drug in generic external turbulent wall-bounded flows. Based on the knowledge of previous studies for flat-plate turbulent boundary layer flow the technique of spanwise traveling transversal surface waves is applied to 74 percent of the surface of a NACA4412 wing section at a chord-based Reynolds number of $Re_c = 400,000$. Different parameter combinations are tested for maximum drag reduction and maximum net power saving. The results show a reduction of the total drag of up to 8.5 percent and a decrease of the viscous drag by up to 12.9 percent. Note that this includes all actuated and non-actuated parts of the surface, i.e., locally a much higher decrease of the wall-shear stress is achieved. Additionally the lift is slightly increased by up to 1.4 percent.

5:19PM B26.00004 Active flow control of the logarithmic layer1, ANNA GUSEVA, MIGUEL P. EMUNAR, JAVIER JIMENEZ. School of Aeronautics, Polytechnic University of Madrid — Active flow control for years has been a vivid topic of fluid dynamics research. It is of especial importance for wall-bounded turbulent flows, where intense dissipation at the wall can produce undesirable effects. One successful control approach is to apply at the boundary a velocity field opposite to the observed in the buffer layer. The focus of this work is on creating a control strategy that can be reproduced in experimental facilities. By acting on the flow from the wall, we aim to affect the eddies of relatively large wavelengths ($h \approx 0.1$) at $Re_c = 1000$. We reconstruct the wall-normal velocity in the log-layer ($y^+ > 100$) with the linear stochastic estimation method. Preliminary implementation of opposition control on the large scales results in substantial drag increase, indicating that we are able to significantly affect those scales and have plenty of control authority. In the conference we present further development of this strategy. We compare the control efficiency of applying different wavelength bands at the wall and check the impact of imposed boundary conditions on the statistics of velocity fluctuations, as well as new structures created in the flow. Finally, we assess the general applicability of our control to the existing measurement techniques.

5:32PM B26.00005 Drag Reduction in the Flow around a Cylinder: A Bayesian Optimization Approach1, ANTHONY LARROQUE, MIGUEL FOSAS DE PANDO. Department of Mechanical Engineering and Industrial Design, University of Cadiz, LUIS LAFUENTE, Department of Mathematics, University of Cadiz — Bayesian Optimization has recently gained popularity as an effective tool to deal with expensive black-box objective functions. Advantages of this method include the ability to determine the global minimum at a reduced number of iterations, and the possibility to include uncertainty in the evaluation of the objective function. Recent developments also include parallel function evaluations or multiple sources of information with varying fidelity. All these features render Bayesian Optimization a promising tool for Direct Numerical Simulations or Large Eddy Simulations, where the computational cost of determining the cost function, such as the drag coefficient, is typically very high, and the computational resources are very limited. In this work, we consider the three dimensional flow around a cylinder and apply Bayesian Optimization to determine the optimal blowing and suction strategy at the wall that leads to a minimum drag coefficient. The efficiency of the resulting optimization scheme is compared to alternative methods. Finally, we discuss the optimal parameters of the velocity profile, the underlying physical mechanisms, and the influence of the Reynolds numbers on the optimal solutions.

Examining the instantaneous and time-averaged velocity distributions, we discuss the relevance of the Stokes boundary layer near the sphere is used to study the physical mechanisms driving DR, which we report between 20% and 30% for $\lambda$. Wings may compensate for changes in spanwise vorticity that induce vortex bursting. Also disrupted on stiffened wings, suggesting that the loss of flexibility gradients contributes to LEV bursting. Flexibility gradients on insect rigid wings, the LEV often bursts but remains attached at Re with well-defined reattachment streaklines. After desiccating, the wings stiffen in both the chord- and spanwise direction, less than the local chord length with well-defined reattachment streaklines. Decreasing the viscosity of the lubricating layer ($\lambda<\lambda_0=4$) from a main layer of fluid (viscosity $\eta_1$) to a thin layer of fluid (viscosity $\eta_2$). To single out the effect of surface tension, we focus initially on two fluids having same density and viscosity, and we then consider a wide range of viscosities of the lubricating layer: from $\lambda=\eta_1/\eta_2=0.25$ (less viscous) up to $\lambda=\eta_1/\eta_2=4.00$ (more viscous). A database comprising DNS of two-phase flow channel turbulence is used to study the physical mechanisms driving DR, which we report between 20% and 30% for $\lambda \leq 1$, 10 % for $\lambda = 2.00$ and absent for $\lambda = 4.00$. The maximum DR occurs when the two fluids have the same viscosity ($\lambda = 1$), and corresponds to the laminarization of the lubricating layer. Decreasing the viscosity of the lubricating layer ($\lambda < 1$) induces a marginally decreased DR, but also helps sustaining strong turbulence in the lubricating layer. This led us to infer two different mechanisms for the two drag-reduced systems, each of which is ultimately controlled by the outcome of the competition between viscous, inertial and surface tension forces.

Saturday, November 23, 2019 4:40PM - 5:58PM — Session B27 Biological Fluid Dynamics: Insect Flight I - Wing Properties 609 - Kai Schneider, Aix-Marseille University

4:40PM B27.00001 Vortex bursting corresponds to reduced gradients in wing flexibility, MEGAN MATTHEWS, BRYAN MCCARTY, SIMON SPONBERG, Georgia Tech — The leading-edge vortex (LEV) is a well-known flight mechanism for flapping insects, but the interplay between the boundary LEV and the flexible wing it attaches to is not yet understood. On rigid wings, the LEV often bursts but remains attached at Re ~ O(10^4). However, this has not been seen on flexible insect wings. Force production increases with decreasing flexural stiffness and further increases when the wing exhibits chord- and spanwise gradients in flexural stiffness. We mounted real hawkmoth wings onto a motor that revolves the wings at a constant frequency and generates a coherent LEV. Using smoke-wire visualization, we observed the qualitative structure of the LEV. On freshly-mounted wings, LEV diameter is consistently 50% or less than the local chord length with well-defined reattachment streaklines. After desiccating, the wings stiffen in both the chord- and spanwise directions, and the LEV formed on stiffened wings has a diameter of at least 80% of the local chord length. The reattachment streaklines were also disrupted on stiffened wings, suggesting that the loss of flexibility gradients on insect wings may compensate for changes in spanwise vorticity that induce vortex bursting.

4:53PM B27.00002 ABSTRACT WITHDRAWN — 5:06PM B27.00003 Unsteady maneuvering of a morphing wing., KAMLESH JOSHI, SAMIK BHATTACHARYA, University of Central Florida — The unsteady flow over a morphing flat-plate airfoil is investigated in this work. The unsteady flow is generated by accelerating the wing from rest and from one steady speed to a higher speed. The plate can be bent smoothly along the span with a flexion ratio of 0.7 and a flexion angle of 20 degree. In these tests, two different bending rates (BR), namely BR = 1s and 2s were implemented. The wing was towed from rest to Reynolds numbers of 10,000 and 20,000, and it was bent simultaneously along the span with zero phase difference between the forward towing motion and the bending motion. Instantaneous forces were measured with a six-dof force sensor, and the flow field was measured with the help of particle image velocimetry. It was found that spanwise bending has a considerable effect on the unsteady forces during acceleration. The vortex dynamics of the leading-edge-vortex was altered due to the variation of the shear layer velocity along the span which occurred due to the bending motion. In this work, we sought to quantify the effect of bending rate on the stability of the leading-edge-vortex. We show that the gradual lifting of the tip vortex closer to the LEV, affects its growth. We also demonstrate that the spanwise bending action alters the added mass peak due to the inertial forces caused by the bending process.

5:19PM B27.00004 Effect of chordwise wing flexibility on the flapping flight of a butterfly-like 3D flapping wing-body model, KOSUKE SUZUKI, TAKAAKI AOKI, MASATO YOSHINO, Shinsyu University — In our recent study [K. Suzuki, T. Aoki, and M. Yoshino, Phys. Rev. E 100, 013104 (2019)], we constructed a flexible wing with chordwise flexibility by connecting two rigid plates with a torsion spring, and investigated the effect of chordwise wing flexibility on the flapping flight of a simple butterfly-like flapping wing-body model by using an immersed boundary-lattice Boltzmann method. First, we investigated the effects of the spring stiffness on the aerodynamic performance when the body of the model is fixed. We found that the time-averaged lift and thrust forces are larger than those of the rigid wings. Second, we simulated free flights when the body of the model can only move translationally. We found that the model with the flexible wings at an appropriate value of the spring stiffness can fly more effectively than the model with the rigid wings, which is consistent with the results when the body of the model is fixed.
5:32PM B27.00005 Numerical simulation of insect flight with flexible wings using a mass-spring fluid-interaction solver. KAI SCHNEIDER, HUNG TRUONG, Aix-Marseille Univ, THOMAS ENGELS, LMD-IPSL, Ecole Normale Superieure-PSL, DMITRY KOLOMENSKY, Japan Agency for Marine-Earth Sci and Tech (JAMSTEC), THE AIFIT TEAM — Fundamental characteristics of insect flight are flexible wings, which play an important role for their aerodynamics. Real wings are delicate structures, composed of veins and membranes, and can undergo significant deformation. Here we present detailed numerical simulations of such deformable wings modeled by a mass-spring network. The mass-spring model uses a functional approach, thus modeling the veins and the membranes of the wing. Results are obtained with a fluid-structure interaction solver, coupling a mass-spring model for the flexible wing with the pseudo-spectral code FLUSI solving the incompressible Navier-Stokes equations. We impose the no-slip boundary condition through the volume penalization method; the time-dependent complex geometry is then completely described by a mask function. We perform a series of numerical simulations of a flexible revolving bumblebee wing at a Reynolds number Re=1800. In order to assess the influence of wing flexibility on the aerodynamics, we vary the elasticity parameters and study rigid, flexible and highly flexible wing models. A better aerodynamic performance of the flexible wing, characterized by the increase of the lift-to-drag ratio, is found while the highly flexible wing appears to be less efficient than the rigid wing.

5:45PM B27.00006 Effect of torsional stiffness on passive wing pitch and its aerodynamic performance in hovering flight. MENGLONG LEI, CHENGYU LI, Villanova University — Insect’s wings are able to passively maintain a high angle of attack due to the torsional flexibility of wing basal region without the aid of the active pitching motion. However, there is no clear understanding of how torsional wing flexibility should be designed to achieve optimal aerodynamic performance. In this work, a computational study was conducted to investigate the passive pitching mechanism of a fruit fly wing in hovering flight using a torsional spring model. The torsional wing flexibility was characterized by Cauchy number. Different flapping patterns including zero-derivation, figure-8, oval-shaped stroke kinematics were evaluated. The aerodynamic forces and associated unsteady flow structures were simulated using an in-house immersed-boundary-method based computational fluid dynamic solver. Our simulations revealed that the optimal lift and lift-to-power ratio can be achieved in a particular range of Cauchy number (0.16~0.30) regardless of its stroke kinematics. This range is consistent with the Cauchy number calculated based on the fruit fly data from literature. The findings of this work could provide important implications for designing more efficient flapping-wing micro air vehicles.

Saturday, November 23, 2019 4:40PM - 6:11PM –
Session B28 Turbulence Theory: Spectral Transfer
601 - Stavros Tavoularis, University of Ottawa

4:40PM B28.00001 Fluctuations in spectral energy transfer and their consequences
SUALEH KHURSHID, DIEGO DONZIS, Department of Aerospace Engineering, Texas A&M University, KATEPALLI SREENIVASAN, New York University — The assumption in Kolmogorov’s seminal work, as well as in all the subsequent work of that genre, is that the average energy transfer across scales is unidirectional, from the large to the smaller, in the case of homogeneous turbulence, from low wavenumbers to high wavenumbers. This assumption would be quite acceptable if the fluctuations in the energy transfer rate were small compared to the mean. But the energy transfer rate is a highly fluctuating quantity, which is nearly as often in the backward direction as forward, and the mean transfer is only a small difference between the two, suggesting the need to consider fluctuations explicitly. In this work, we characterize the fluctuations in wavenumber space, of the energy itself and energy transfer rate, for a range of Reynolds numbers, using highly resolved direct numerical simulations. The simulations allow us to study dynamical interactions across scales and quantify the trade-offs between such as localness or otherwise of energy transfer in the spectral space. We show that the total transfer rate is indeed local in wavenumber space, though the information about large scales is preserved by means of the low-frequency and low-amplitude fluctuations that traverse from low to high wavenumbers with increasing time lag.

4:53PM B28.00002 Emergence of turbulent behavior for passive scalars
DIEGO DONZIS, Texas A&M University, K.R. SREENIVASAN, NYU, V. YAKHOT, Boston University — We recently identified a transition to strong turbulence in isotropic turbulence with stochastic forcing. We found that the higher the order of the derivative moment the lower the transition Reynolds number. By a suitably rescaling, we could reduce the transition value to a universal Reynolds number of the order 10 for all orders. The moments of velocity gradients are Gaussian below this transition Reynolds number and exhibit anomalous scaling above, with the same scaling exponents as high-Reynolds-number turbulence. The matching of the two asymptotic states led to analytical expressions for scaling exponents in excellent agreement with available data. In this work we extend these concepts to passive scalar mixing. We observe a similar type of transition with the same Gaussian asymptotic behavior at low Reynolds numbers, but the transition Reynolds number depends on the Schmidt number (the ratio of viscosity to scalar diffusivity), and the matching of the two regimes yields scaling exponents that depend on the Schmidt number. The connection with the so-called ramp-cliff structures is also discussed. As for the velocity field, these results suggests that high-Reynolds-number behavior can be studied via well-resolved simulations around this low-Reynolds-number transition.

5:06PM B28.00003 Third-order structure functions for isotropic turbulence with bidirectional energy transfer
JIN-HAN XIE, College of Engineering, Peking University, OLIVER BUHLER, Courant Institute of Mathematical Sciences, New York University — We derive and test a new heuristic theory for third-order structure functions that resolve the forcing scale in the scenario of simultaneous spectral energy transfer to both small and large scales, which can occur naturally in rotating stratified turbulence or magnetohydrodynamical turbulence, for example. The theory has three parameters, namely the upscale/downscale energy transfer rates and the forcing scale, and it includes the classic inertial range theories as local limits. When applied to measured data, our global-in-scale theory can deduce the energy transfer rates using the full range of data, therefore it has broader applications compared with the local theories, especially in the situations where the data is imperfect. In addition, because of the resolution of forcing scales, the new theory can detect the scales of energy input, which was impossible before. We test our new theory with a two-dimensional simulation of MHD turbulence and use the theory to analysis geophysical fluid data.
5:19PM B28.00004 Inter-scale energy transfer by multiscale vorticity stretching and strain self-amplification in turbulence. PERRY JOHNSON, Stanford University — Three-dimensional turbulent flows are characterized by net transfer of energy from large to small scales. This inter-scale energy transfer is commonly described as a cascade driven by vorticity stretching, but in a phenomenological or imprecise way. Somewhat less commonly, the role of strain self-amplification is emphasized. This talk demonstrates an exact expression for inter-scale energy transfer in terms of multiscale vorticity stretching and strain self-amplification. This relationship elucidates the relative role of two of these two mechanisms in driving the cascade in the inertial range, while also accounting for the relative importance of scale-local and scale-nonlocal processes. Direct numerical simulations show that strain self-amplification contributes more to the energy cascade than vorticity stretching, but not overwhelmingly so. The leaky cascade view of inter-scale energy transfer is supported by the results. An additional mechanism of inter-scale energy transfer is revealed, with a possible connection to two-dimensional turbulence.

5:32PM B28.00005 Interscale Transport of the Reynolds Shear Stress in Wall-bounded Flows. RAMIS ORLÜ, Linné FLOW Centre, KTH Mechanics, GIOLE FERRANTE, ANDRES MORFIN, Università di Bologna, TAKUYA KAWATA, Tokyo University of Science, PHILLIP SCHLATTER, P. HENRIK ALFREDSSON, Linné FLOW Centre, KTH Mechanics — The interplay between the inner and outer layers in wall-bounded turbulent flows has become one of the focus areas with the advent of high-fidelity numerical and experimental data of sufficient scale separation, i.e. high enough Reynolds number. The general view is that the inner layer behaves autonomously in terms of its near-wall cycle and the outer layer exhibits independence of the details of the inner layer. At the same time, strict inner scaling for the near-wall region does not hold, due to the top-down influence from the large-scale structures further away from the wall. Recently, bottom-up influence (inverse energy transfer) has been observed, but primarily studied in terms of the turbulent kinetic energy. Here, using numerical simulation data from both a plane Couette flow and a turbulent boundary layer, the interscale transport of the Reynolds stresses is examined. Besides the classical interscale transport of turbulent kinetic energy towards smaller scales, also an inverse interscale transport of the Reynolds shear stress was observed. The spectral, scale-by-scale, analysis also indicates how interscale transport and turbulent diffusion explains the mismatch between the locations of the outer peaks in the Reynolds shear stress production and cospectrum.

5:45PM B28.00006 Impact of large-scale flow states on small-scale 3D turbulence. CRISTIAN C LALESCU, MICHAEL WILCZEK, Max Planck Institute for Dynamics and Self-Organization, Goettingen — Turbulent flows often feature an intricate interplay between anisotropic, even quasi-two-dimensional, large-scale features and three-dimensional small-scale fluctuations. To systematically study the relationship between large-scale flow structures and small-scale turbulence, we investigate a conceptually simple shear flow — a generalized turbulent Kolmogorov flow. The flow is forced with a single shear mode and is subject to large-scale friction, which effectively allows to control transitions between different large-scale states. We present a detailed investigation of the energetics of the system, and we find that the excitation of three-dimensional small-scale turbulence provides a direct kinetic energy cascade from large to small scales in the sense of classical eddy viscosity. We show that the energy transfer rate depends on the large-scale flow state, which establishes a direct coupling between the large scales and smaller-scale flow features such as small-scale intermittency.

5:58PM B28.00007 Energy flux vectors in two-dimensional anisotropic turbulence. MASANORI TAKAOKA, Department of Mechanical Engineering, Osaka University, TAKUYA KAWATA, Tokyo University of Science, PHILLIP SCHLATTER, P. HENRIK ALFREDSSON, Linné FLOW Centre, KTH Mechanics, GIOLE FERRANTE, ANDRES MORFIN, Università di Bologna, Bologna, TAKUYA KAWATA, Tokyo University of Science, PHILLIP SCHLATTER, P. HENRIK ALFREDSSON, Linné FLOW Centre, KTH Mechanics — The interplay between the inner and outer layers in wall-bounded turbulent flows has become one of the focus areas with the advent of high-fidelity numerical and experimental data of sufficient scale separation, i.e. high enough Reynolds number. The general view is that the inner layer behaves autonomously in terms of its near-wall cycle and the outer layer exhibits independence of the details of the inner layer. At the same time, strict inner scaling for the near-wall region does not hold, due to the top-down influence from the large-scale structures further away from the wall. Recently, bottom-up influence (inverse energy transfer) has been observed, but primarily studied in terms of the turbulent kinetic energy. Here, using numerical simulation data from both a plane Couette flow and a turbulent boundary layer, the interscale transport of the Reynolds stresses is examined. Besides the classical interscale transport of turbulent kinetic energy towards smaller scales, also an inverse interscale transport of the Reynolds shear stress was observed. The spectral, scale-by-scale, analysis also indicates how interscale transport and turbulent diffusion explains the mismatch between the locations of the outer peaks in the Reynolds shear stress production and cospectrum.

Saturday, November 23, 2019 4:40PM - 6:11PM – Session B29 Biological Fluid Dynamics : Respiratory Flows II

4:40PM B29.00001 A dynamical systems approach to particle transport in lung airways. ALI FARGHADAN, Northern Arizona University, FILIPPO COLETTI, University of Minnesota, AMIRHOSSEIN ARZANI, Northern Arizona University — Computer modeling of respiratory flows and particle transport are of both physiological and toxicological interests. In this talk, we present hidden dynamical systems features that control transport in human conducting airways. High-resolution computational fluid dynamics (CFD) simulation is carried out for an image-based tracheobronchial model under sinusoidal respiration flow. The destination map, which synchronizes the particle destination on the release point is found after performing Lagrangian particle tracking for microparticles. Finite-time Lyapunov exponent (FTLE) is calculated and inertial Lagrangian coherent structures (ILCS) are tracked during the breathing cycle. The results show that these dynamical systems features control the spatiotemporal evolution of the destination map at the trachea. Finally, slow manifolds are used as an efficient technique to identify the source of any arbitrary particle with backward integration of the Maxey-Riley equation. The novel dynamical systems techniques presented have important implications for drug delivery in respiratory disease.

JSPS KAKENHI Grant No. 18K03927, 19K03677
4:53PM B29.00002 Can we use CFD to improve targeted drug delivery in throat?1
SAIKAT BASU, South Dakota State University, RUPALI SHAH, ANDREW PAPPA, JIHONG WU, ALYSSA BURKE, WILLIAM BENNETT, WANDA BODNAR, JULIA KIMBELL, University of North Carolina at Chapel Hill — Numerical simulations of respiratory airflow and particle transport, along with synergistic physical experiments, can be used to identify the nebulized particle sizes that are most effective in enhancing targeted deposition at the laryngeal vocal fold granulomas in human throats. Narrow tracheal geometry results in high-speed inhaled airflow, leading to transitional and turbulent flow features. To account for short time-scale effects such as vortices, which can affect particle transport, our computational modeling scheme implements Large Eddy Simulations (LES) in three CT-derived anatomical mouth-nose-trachea reconstructions. To validate the numerical predictions, two distinct in vitro techniques, namely gamma scintigraphy and mass spectrophotometry, are used for measuring topical deposition in one CT-based solid model. Findings suggest a specific range \( \approx 8 – 10 \, \mu\text{m} \) of particle sizes with laryngeal granulomas and glottis as the specific deposition sites. The study considers three granuloma sizes (small, 3 mm; medium, 4.5 mm; large, 6 mm diameter) positioned at three distinct locations along the tissue lining of the vocal folds. The results have the potential to come up with novel personalized therapy protocol.

1Supported jointly by the National Center for Advancing Translational Sciences (NCATS), of the National Institutes of Health (NIH), through grant award UL1TR002489; and by the National Heart, Lung, and Blood Institute (NHLBI) of the NIH, under award R01HL122154

5:06PM B29.00003 Role of two-phase air-mucus interaction on aerosolized drug delivery in idealized lung models , RAHUL RAJENDRAN, ARINDAM BANERJEE, Lehigh University — Aerosolized drug delivery to the lung airways depends on the particle size, breathing pattern, and the airway geometry. The influence of the two-phase flow morphology and the local airflow structures developed in the mucus-lined airways of obstructive airway diseases, on the deposition of inhaled drugs is investigated. The Lagrangian particle tracking model is coupled with the multiphase Eulerian-Eulerian model to investigate the gas-liquid-solid flow in 3D idealized airway geometries. Mucus is modeled as a non-Newtonian fluid using the power-law equation, and flow turbulence is modeling using the low-Re \( k-\omega \) SST model, including the eddy interaction model (EIM) for the particles. The results from the study are validated with experimental results from the literature and comparisons with constricted dry-wall airways are presented. The role of mucus rheology, airflow rate, particle size, airway geometry and gravity are discussed. A quantitative assessment on the global and regional deposition fractions of the particles, sites of deposition, clearance rates, pressure drop across the airway, and airway resistance in mucus-lined airways will be presented.

5:19PM B29.00004 Effect of viscoelasticity and surfactant on an airway closure model1 , FRANCESCO ROMANO'. University of Michigan & ENSAM - ParisTech, HIDEKI FUJIOKA, Tulane University, METIN MURADOGLU, Koc University, JAMES B. GROTBERG, University of Michigan — A liquid made out of mucus and serous layers lines the human lung airways. Several different flow regimes are observed depending on the generation of the bifurcation and when small airways are considered (9th or 10th generation of the airway tree), surface tension effects dominate and they can induce a Plateau-Rayleigh instability. The airway is modeled as a rigid pipe coated with a single-layer fluid and the effects of surfactant and non-Newtonian properties of mucus are investigated using numerical simulations. The viscoelasticity of mucus is taken into account by means of the Oldroyd-B model, whereas surfactant is considered for a Newtonian lining fluid. The evolution equations of the interfacial and bulk surfactant concentrations are solved coupled with the incompressible Navier–Stokes equations. The viscoelastic behavior of mucus strongly increases post-coalescence wall shear stresses (about 50% in their peak value) when the Laplace number is high, whereas pre-coalescence stresses are almost insensitive to the Weissenberg number. Surfactant has a negligible effect on the closure-induced shear stress, except when the elasticity parameter or the surfactant concentration is high enough. Our parametric study covers both, healthy and pathological conditions.

5:32PM B29.00005 Effect of viscoelasticity and surfactant on the propagation and rupture of a liquid plug in an airway1 , METIN MURADOGLU, Koc University, FRANCESCO ROMANO'. University of Michigan & ENSAM - ParisTech, HIDEKI FUJIOKA, Tulane University, JAMES B. GROTBERG, University of Michigan — The propagation and rupture of a liquid plug in a distal airway are studied using numerical simulations. The simulations are carried out using a finite-difference/front-tracking method, previously validated for airway reopening with Newtonian fluids. The airway walls are considered rigid and the plug is driven by a pressure gradient enforced between the extrema of the pipe. The effect of interfacial and bulk surfactant is considered, together with the viscoelasticity of mucus, which is here taken into account using the FENE-P model. Our parametric study shows that the presence of surfactant can efficiently reduce the wall stresses along the airway wall, hence surfactant helps to reduce the damage on the epithelial cells distributed along the internal surface of an airway. Moreover, the effect of several viscoelastic parameters is considered, such as the Weissenberg number, the length of the polymer and the polymer-to-solvent viscosity ratio. Particular attention is paid to the distribution of extra stresses due to the non-Newtonian behavior of mucus since interesting elastic dynamics are triggered by the liquid plug rupture over the liquid-gas interface.

5:45PM B29.00006 Computational investigation of plug flow dynamics and splitting through 3D multi-branching bifurcating lung airway models , CORY HOI, University of Massachusetts, Dartmouth, ASHISH PATHAK, MEHDI RAESSI, University of Massachusetts Dartmouth — Liquid plug flow in capillary tubes has applications in medical procedures, including surfactant replacement therapy (SRT), which is used to treat respiratory distress syndrome in preterm infants by delivering surfactant plugs to their lungs. Current SRT procedures have a 35% non-response rate, which has been attributed to the complex fluid dynamics of liquid plug propagation through the lung airway network. Previous computational works performed 2D investigation of plug splitting in a single bifurcating airway geometry and mathematical models have been developed to calculate the plug split ratio at each independent airway bifurcation. In contrast, we present 3D CFD simulations of surfactant plug transport through multi-branching bifurcating lung airway models with three generations, in which upstream flows show a strong dependence on the downstream flow behavior of previously instilled plugs in subsequent airway generations, a phenomenon not captured in previous computational studies. Our simulations investigate the effects of plug instillation frequency, downstream plug blockages and plug rupture on plug split ratio and distribution, improving our understanding of SRT and helping to increase its effectiveness.
Accumulation of low-density lipoprotein (LDL) on the lumen surface of blood vessels is central to the initiation and progression of many cardiovascular diseases. It has been found that, in high Schmidt number flows, it is the near-wall flow dynamics that dictate the transport and accumulation of LDL. The mechanisms of fluid transport by cilia have been studied extensively at the level of the individual cilium and metachronal waves. However, how the topology of ciliary arrays is optimized to generate organ-scale directed flows is largely unexplored. Here, we image the mouse airway to map the geometry of its ciliary carpet, from the sub-cellular (10−6 m) to the organ scales (10−2 m), characterizing quantitatively its ciliary arrangement and the generated flows. Locally we measure heterogeneity in both cilia organization and flow structure, but across the trachea fluid transport is coherent. To examine this result, we develop a hydrodynamic model to explore systematically different tissue architectures. Surprisingly, we find that disorder enhances particle clearance, whether it originates from fluctuations, heterogeneity in multiciliated cell arrangement or ciliary misalignment. Together, our results shed light on how the microstructure of an active carpet determines its emergent dynamics and are applicable to understand airway pathologies.

Saturday, November 23, 2019 4:40PM - 6:11PM – Session B30 Biological Fluid Dynamics : Microfluidics 612 - C. Nadir Kaplan, Virginia Tech

4:40PM B30.00001 Thermal Effects on Fluid Mixing in the Eye1, JINGLIN HUANG, MORTEZA GHARIB, Caltech — Age-related macular degeneration (AMD) is the leading cause of central vision loss in the developed world. In the case of wet AMD, it can be managed through serial intravitreal injections of anti-vascular endothelial growth factor (anti-VEGF) agents. However, sometimes the treatment is ineffective and causes side effects. One possible cause of the ineffective treatment is the inefficient fluid mixing in the eye. Continued from my talk last year, we are now focusing on the understanding of thermal effects on fluid mixing in the vitreous chamber and various parameters that could affect it. The study outcomes will be useful for inspiring eye doctors to develop better strategies for improving treatment efficiency and optimizing patient experience.

4:53PM B30.00002 Computational analysis of interstitial fluid flow through the lacunar-canalicular system with morphological variations. SHAILESH KHADANGALE, SAMIRA HAJEBRAHIMI, MAUREEN LYNCH, DEBANJAN MUKHERJEE, University of Colorado Boulder — Osteocytes play a central role in maintenance of skeletal structure and associated mechanobiological processes. Interstitial fluid flow in the lacunar-canalicular system (LCS) is pivotal for osteocyte mechanotransduction but is challenging to model. For this we developed a CFD framework, based on Stokes-Brinkman model with variable permeability, for interstitial fluid flow in the LCS, and quantify shear at the osteocyte wall. We used our framework to quantify variations in shear due to changes in LCS morphology observed in metastatic bone cancer. A range of parametrically varied LCS morphologies were modeled based on lacuna dimensions and position data from micro-CT scan of healthy and cancerous mouse tibia. Shear on osteocytes was quantified for the various LCS morphologies considered to obtain bounds on osteocyte shear based on knowledge of lacuna shape and dimensions alone. Also, shear variations on osteocytes resulting from LCS morphology variations from neighboring sites were quantified. Our study revealed significant shear stress variations across all LCS morphological variations. Our over-arching theme is to advance this model into a computational toolkit to generate and test hypotheses on the role of shear mechano-transduction in metastatic bone cancer.

5:06PM B30.00003 Experimental modeling of fluid homeostasis in the mammalian hearing organ1, RUY IBANEZ, MOHAMMAD SHOKRIAN, JONG-HOON NAM, DOUGLAS H. KELLEY, University of Rochester — The mammalian hearing organ (cochlea) contains a long microfluidic channel (channel width ≈ 50 μm and aspect ratio ≈ 700). Ex vivo observations have shown that auditory stimulations induce deformations, in the form of a travelling wave, on the walls of the microfluidic channel and produce a flow. By determining the relevant physical parameters in the channel and applying scaling laws, we designed an apparatus that can replicate the physical conditions of the inner ear channel. We seek to characterize the induced flow using particle tracking velocimetry measurements, as well as characterizing the Lagrangian dynamics using a particle advection code. We validate the experimental measurements by comparing to previous analytic results. We study the effect of channels end boundary conditions (open or closed) and the shape of the wall deformation on the flow dynamics. We also find good agreement with finite-element simulations.

5:19PM B30.00004 Prediction of Low-density Lipoprotein Concentration on the Luminal Surface of Pathological Blood Vessels Using Wall Shear Stress. SATYA JIT CHOUDHURY, Department of Applied Mechanics, Indian Institute of Technology Madras, KAMESWARARAO ANUPINDI, Department of Mechanical Engineering, Indian Institute of Technology Madras, B.S.V PATNAIK, Department of Applied Mechanics, Indian Institute of Technology Madras — Accumulation of low-density lipoprotein (LDL) on the lumen surface of blood vessels is central to the initiation and progression of many cardiovascular diseases. It has been found that, in high Schmidt number flows, it is the near-wall flow dynamics that dictate the transport and accumulation of the LDL on the lumen surface. Since wall shear stress (WSS) offers a reasonable approximation of near-wall flow dynamics, our study utilizes WSS to predict the variation of concentration of LDL on the lumen surface of symmetric 2D as well as asymmetric 3D pathological arteries. Blood is considered as Newtonian, incompressible and modeled using the Navier-Stokes equation whereas, the transport of LDL is governed by the passive scalar advection-diffusion equation. Even though the flow is pulsatile, it is found that time-averaged WSS gives a very good prediction of the variation of LDL concentration on the lumen surface. It is seen that low WSS need not necessarily lead to high LDL concentration. The influence of the stagnation points (region of zero WSS) on LDL concentration is also explored in the present work.
5:45PM B30.00006 Examining role of composition on the formation of extracellular polymeric substance (EPS) aggregates over a rising oil micro-droplet under shear. JIAN SHENG, MUN MUN NAHAR, ANDREW WHITE, MARYAM JALALI, Texas A&M. After Deepwater Horizon spill, it is believed that up to 15% of released oil settled to the sea floor as marine oil snow (MOS), which has been corroborated by field and laboratory observations. Several factors contributed to the production of MOS including particulate concentration and microbial mucous (e.g. EPS). EPS is a complex mixture of polysaccharides, proteins, nucleic acids and lipids, and their composition can vary significantly based on the microbial community and the environment. To examine quantitatively the role of EPS composition, specifically protein to hydrocarbon ratio (PHR), on aggregation, we use a microfluidics, “ecology-on-a-chip”, to simulate an rising oil drop through a suspension containing EPS and particulates. Time lapse microscopy lasting several days captures the growth and morphology of EPS aggregates. We demonstrate that EPS in the absence of particles is unable to form aggregates, while the addition of particles induces rapid aggregation. The higher PHR results in more stickiness of the EPS molecule and consequently leads to larger and more rapid formation of MOS. Ongoing work is considering the influence of flow shear and various EPS conformation on aggregate formation in flows. Funded by GoMRI & ARO.

Saturday, November 23, 2019 4:40PM - 6:11PM – Session B31 Biological Fluid Dynamics: Micro-swimmer Computational

4:40PM B31.00001 Instabilities and dynamics of phoretic suspensions1, TULLIO TRAVERSO2, SEBASTIEN MICHELIN, Ecole Polytechnique. Suspensions of Janus phoretic colloids are a canonical example of synthetic active fluids. Their potential applications range from technological to medical ones. Individual microscopic particles self-propel as a result of self-generated chemical gradients, and influence each other hydrodynamically and chemically. Such interactions lead to spontaneous nontrivial dynamics within phoretic suspensions, on length scales much larger than the swimmer size. We use a kinetic model to investigate the competition and interaction of self-propulsion with hydrodynamic and chemical couplings, whose characteristics are fundamentally determined by the shape and surface chemical properties of the particle, which are design parameters that can be optimized and controlled. Using a combination of linear stability analysis and nonlinear numerical simulations, we discuss the role of such design parameters in determining the onset of instabilities and subsequent nonlinear collective dynamics in dilute suspensions of chemically-active Janus swimmers.

4:53PM B31.00002 The role of shape for a Brownian microswimmer interacting with walls. JEAN-LUC THIFFEAULT, HONGFEI CHEN, University Of Wisconsin - Madison. We consider a simple model of a two-dimensional microswimmer with fixed swimming speed. The direction of swimming changes according to a Brownian process, and the swimmer is interacting with boundaries. This is a standard model for a simple microswimmer, or a confined wormlike chain polymer. The shape of the swimmer determines the range of allowable values that its degrees of freedom can assume — its configuration space. Using natural assumptions about reflection of the swimmer at boundaries, we compute the swimmer’s invariant distribution across a channel consisting of two parallel walls, and the statistics of spreading in the longitudinal direction. This gives us the effective diffusion constant of the swimmer’s large scale motion. When the swimmer is longer than the channel width, it cannot reverse, and we then compute the mean drift velocity of the swimmer. This model offers insights into experiments of scattering of swimmers from boundaries, and serves as an exactly-solvable baseline when comparing to more complex models.

5:06PM B31.00003 Simulation and fabrication of neuromuscular biohybrid swimmers1, MATTIA GAZZOLA, ONUR AYDIN, XIAOTIAN ZHANG, TAHER SAIF, University of Illinois, Urbana-Champaign. Biohybrid machines have been developed using muscles to actuate soft robotic structures. The integration of neurons into the embodiment of such systems can transform them into intelligent machines able to adaptively respond to environmental cues. This relies on the ability of neural units to command muscle activity, making actuation through motor neurons the first milestone. Here, we achieve this milestone, and demonstrate neuromuscular actuation of a computationally designed biohybrid swimmer.

Reynolds number and elucidate the fundamental insights obtained. We expect our work to shed some light on the importance of stratification expenditure, hydrodynamic efficiency and the induced mixing by the swimmer. We explore this dependence in detail for both the regimes of field around the swimmer. This has a direct consequence on the motility characteristics of the swimmer such as swimming velocity, power or salinity. We divide our analysis in two regimes of low and high Reynolds numbers. We find that stratification significantly alters the flow study finds a direct application for swimmers in oceanic waters, where stratification occurs naturally either due to gradients in temperature or salinity. We divide our analysis in two regimes of fluid and elastic swimmer parameters when using noisy swimmer trajectory data at 30 Hz. This methodology can be used to develop artificial micro-swimmers and understand parameter ranges that allow for certain motility patterns.

According to the references, we can find insights into the locomotion of organisms living in such environments. For instance, Jeffery (1922) and Gustavsson and Mehlig (2016) provide foundational work in this area. These studies have implications for both plankton ecology and medical applications, where precise control over swimming behavior is crucial. Direct numerical simulations (DNS) can be used to integrate the Lagrangian trajectories of particles swimming in turbulence with fixed speed and orientation governed by fluid gradients. Swimmers elongated along their swimming axis, align with the local flow velocity, with preferential downstream swimming. By the perturbative solution of a statistical model, we can show how the alignment is due to the peculiar correlation of fluid velocity and its gradients along particle paths caused by swimming. Numerical computation of the relevant correlations in DNS results shows that the theoretical prediction applies with remarkable precision to turbulent flows.

In silico modeling of formation and growth of thrombus under blood flow.

4:53PM B32.00002
NIKHIL JANARDAN YEWALE, SATYAJIT CHOUDHURY, B.S.V PATNAIK, Department of Applied Mechanics, Indian Institute of Technology Madras. — Understanding the spatio-temporal evolution of thrombus — biochemical species is critical to simulate the initiation and propagation of pathways that lead to thrombus formation in blood vessels. A large number of species and their reactions are challenging to synthesize through the experimental means. Thus, in silico modeling of the blood clot formation serves as a useful tool. To this end, blood is assumed as a multi-constituent mixture comprising of fluid and thrombus phase, which transports various biochemical agonists and inhibitors contributing to the coagulation cascades. In this study, blood is modeled using source term to account for the resistance on the blood flow from the thrombus formed. The transport of biochemical species involved is represented with convection-diffusion-reaction equations. The injury site is subjected to a constant influx of chemical agonist. The model used in this study accounts for the embolization of clot due to shear stress. We present the CFD simulation of the growth of thrombus at the site of endothelial injury due to chemical and shear-induced activation of platelets in a straight and stenosed blood vessel. The study also highlights the influence of flow pulsatility on the growth of thrombus.

On cell proliferation in a tissue engineering scaffold pore, effects of nutrient concentration and scaffold internal geometry.

ZESHUN ZONG, Courant Institute, New York University, XINYU LI, New York University, Shanghai, PEJIAN SANAEI, New York Institute of Technology. — Cell proliferation within a porous tissue engineering scaffold perfused with nutrient solution depends sensitively on the choice of pore geometry, flow rates, and nutrient concentration. Regions of high pore curvature encourage cell proliferation, while a critical flow rate is required to promote growth. Moreover, the dynamics of the nutrient culture medium consumption influence the cell growth. In experiments, such factors should be chosen meticulously to match the characteristics of the underlying cells and the particular goal of incubation. However, determining these factors poses a significant challenge that cannot be addressed by experimentation alone. In this talk, we present the first-principle mathematical theory for the nutrient concentration coupled to the growth of cells seeded on the pore walls, which is driven by the fluid flow within a tissue engineering scaffold pore. In addition, using asymptotic analysis based on the pore small aspect ratio, we derive a reduced model that enables a comprehensive analysis of the system to be performed. This approach reduces the number of parameters, captures the experimental observations and suggests improvements to the design of a tissue engineering scaffold and the appropriate operating regime.

An Assessment of Thrust, Drag, and Momentum Exchange of Undulation-Based Propulsion.

GEORGE LOUBIMOV, MICHAEL KINZEL, University of Central Florida. — Studies have shown increases in efficiency for undulating propulsion through interactions with unsteady wakes. Specifically, performance gains are related to favorable interactions between an undulation-like swimmer and an oncoming, unsteady wake such as that of a schooling fish. In this study, Computational Fluid Dynamics (CFD) is used to evaluate the unsteady fluid interactions associated with undulation-based propulsion. The numerical accuracy of the CFD model is established and also shown to correlate well with benchmark experiments. While a number of methods have been used to design an undulation-based swimmer, the above approach is based on the use of unsteady wakes, the fundamental physics of the fluid mechanics responsible for propulsion is not fully understood. The aim of the effort is to refine the understanding of the forces associated with the unsteady wakes on an undulating foil. It is proposed that through evaluating the total pressure changes, shear force, and volume momentum changes during these interactions, additional insight can be developed. Using this approach, we believe we can identify the key fluid criteria responsible for increasing the propulsive efficiency of undulating swimmers.

Pumping at low Reynolds numbers - the leucon sponge pump.

JENS HONORE WALTHER, SAYED SAED ASADZADEH, POUL SCHEEL LARSEN, Technical University of Denmark, HANS ULRIK RISGRD, University of Southern Denmark. — Leucon sponges are filter-feeders with a complex system of branching inhalant and exhalant canals leading to and from the close-packed choanocyte chambers. Each of these choanocyte chambers holds many choanocytes that act as pumping units delivering the relatively high pressure rise needed to overcome the system pressure losses in canals and constrictions. We study these pumping units by solving the Navier-Stokes equations using computational fluid dynamics simulations. We find that each choanocyte acts as a leaky, positive displacement pump working at the interaction between its beating flagellum and the collar, open at the base for inflow but sealed above. The leaking backflow is caused by small gaps between the vaned flagellum and the collar. The choanocyte pumps act in parallel, each delivering the same high pressure, because low-pressure and high-pressure zones in the choanocyte chamber are separated by a seal – secondary reticulum. The mechanical pump power expended by the beating flagellum is compared with the useful (reversible) pumping power received by the water flow to arrive at a typical mechanical pump efficiency of about 70%.

Fluid Dynamics of Ballistic Strategies in Nematocyst Firing.

CHRISTINA HAMLET, Bucknell University, WANDA STRYCHALSKI, Case Western Reserve University, LAURA MILLER, University of North Carolina at Chapel Hill. — Nematocysts are stinging organs used by members of the phylum Cnidaria (jellyfish, anemones, hydra) for capturing prey and other important functions. Nematocysts are some of the fastest-known accelerating structures in the animal world. As such their rapid accelerations and small scales complicate resolving some aspects of their firing mechanism. We present results from mathematical models implemented in an immersed boundary framework that capture some of the dynamics of a a Barb-like structure accelerating a short distance across a range of Reynolds numbers toward a passive target. Results indicate that acceleration and then coasting is not sufficient for a nematocyst to reach its target. We discuss the implications of these results for mechanisms required for small-scale ballistics.

5:58PM B32.00007
Growth and adaptation in a fungal hydraulic network.

BOHYUN KIM, UCLA Math, JOSEPH BECKMANN COLLABORATION, MATTHEW CHEUNG COLLABORATION, JOHN LENTFER COLLABORATION, RAMONA SASSE COLLABORATION. — Biological networks such as fungal hydraulic networks have evolved to solve many of the same problems as human-built transportation networks. However, they must also briskly adapt to changing environments and modify their architecture without centralized control. Working with the model filamentous fungus, Neurospora crassa, we characterize the growth of the network and propose a mathematical model for the collaborative behavior of its cells at various scales. We compare our model with measurements of the complex distribution of flows and resources across the cellular network.

Session B33 Flow Instability: Viscoelastics
615 - Marie-Charlotte Renoult, INSA de Ronen
4:40PM B33.00001 Experimental investigation Faraday wave onset in viscoelastic materials\textsuperscript{1}. XINGCHEN SHAO, J. R. SAYLOR, JOSHUA BOSTWICK, Clemson University, PASQUALE CIARLETTA, Politecnico di Milano — Herein we explored the onset of parametrically excited surface waves (Faraday waves) on glycerin-water mixtures and agarose gels, ascertaining the effect of viscosity and elasticity on the threshold amplitude and mode selection. Faraday waves were mechanically generated in a circular tank mounted on an electromechanical shaker over a range of driving frequencies. We obtained multiple Faraday instability modes, each of which is characterized by a radial and azimuthal wave number and by a unique stability tongue in the amplitude-frequency space. Glycerin/water mixtures were used to explore a range of viscosities showing that for a given mode the frequency at onset decreases with viscosity, while the amplitude increases. In contrast, for gels, the onset frequency and amplitude both increase with elasticity. Experiments are then compared against theory. This work could potentially be used to develop a diagnostic method for measuring the complex modulus of viscoelastic materials.

\textsuperscript{1}Funding support from NSF Grant CBET-1750208 is acknowledged

4:53PM B33.00002 Viscoelastic flow instabilities in static mixers: onset and effects on the mixing efficiency. SIMONA MIGLIOZZI, GIOVANNI MERIDIANO, LUCA MAZZEI, PANAGIOTA ANGELI, Dept. of Chemical Engineering, University College London, CORAL COLLABORATION — Purely elastic instabilities occur in the absence of inertial effects, induced by the combination of strong elastic forces with nonlinearities of the flow. In a laminar mixing process, the onset of these instabilities is likely to occur in the window of applied flow rates, therefore it is of paramount importance to understand the effects of their onset on the mixing efficiency. In this work, we experimentally investigate the onset of elastic instabilities in two in-line mixers with different geometric features, i.e. a Kenics helical mixer and a GFX mixer, characterised by a double X-shaped bars geometry. Concentrations maps were obtained at different mixer lengths by means of Planar Laser Induced Fluorescence. We mapped the onset of the instabilities with Reynolds and Deborah numbers. Three fluids with different rheological behaviour – i.e. a Boger fluid and two shear-thinning fluids – were tested to deduced a generalised effect of the fluid elasticity on the mixing patterns. The effect of the instabilities depended on the different kinematics induced by the two distinct geometries: for the helical mixer the typical lamellar structure is not recovered and the two liquid streams remain unmixed, while for the GFX mixer the concentration maps oscillate in time in a quasi-periodic fashion. In both cases, the onset of instabilities worsens the mixing efficiency with respect to the Newtonian case.

5:06PM B33.00003 Three-dimensional viscoelastic flow instabilities at extensional stagnation points. BECCA THOMASES, PALOMA GUTIERREZ, ADAM KAGEL, University of California, Davis — Simulations of viscoelastic fluid models in the Stokes limit exhibit instabilities at extensional stagnation points. We present simulations of both the Oldroyd-B and FENE-P models in a 3D periodic domain with cylindrical 4-roll mill background forcing. Beyond a critical Weissenberg number (non-dimensional relaxation time) we find an instability in the z-direction (note that the background force is constant in z). We present both simulations and linear stability analysis and identify criteria for the occurrence of this instability.

5:19PM B33.00004 Proper orthogonal decomposition of viscoelastic liquid jets. LOUISE COTTIER, MARIE-CHARLOTTE RENOUlt, CORIA-UMR 6614 INSA Rouen Normandy, CHRISTOPHE DUMOUCHEL, CORIA-UMR 6614 CNRS — Proper Orthogonal Decomposition (POD) is a linear procedure that allows to identify characteristics of a data set by determining an optimized set of function basis. The optimization of that new basis is achieved by maximizing the projection of the data set on it. POD therefore depends on the choice of the scalar product. In the field of fluid dynamics, POD has been mostly applied to single phase turbulent flows, using the classical Euclidean scalar product. Here, we apply POD to a two-phase laminar flow: a low-velocity viscoelastic liquid jet evolving in an inert gas. More precisely, the procedure is applied to the interface between the two phases, and the scalar product is sought in the aim of tracking the jet surface evolution. After a brief presentation of the POD concept, we will describe the operating of our POD procedure on viscoelastic liquid jet images obtained from our experiments. Then, the results regarding pattern identification will be exposed. Finally, we will state what kind of physical information POD could bring about an atomization process involving viscoelasticity.

5:32PM B33.00005 Analysis for inertial and elastic instabilities in extensional flow and comparisons with cross-slot flow. HOWARD HU, RANJIANGSHANG RAN, PAULO ARRATIA, University of Pennsylvania, H. HU, R. RAN AND P. ARRATIA TEAM — We theoretically investigate the instabilities of a steady planar extensional flow of viscoelastic fluids with the flow vorticity equation. The results of this linear stability analysis indicate two distinct instabilities depending on the values of Reynolds number (Re) and Weissenberg number (Wi). One instability is an inertia-dominated one occurring at a critical Re, in which the vorticity component $\omega_z$ becomes unstable, suggesting an emerging axial vortex in the extensional direction $x$. The other instability is an elasticity-dominated one at high Wi, where the vorticity component $\omega_z$ in the direction normal to elongational plane becomes unstable, indicating a symmetry breaking on the elongational $xy$-plane. The predicted critical $Re$ and $Wi$ numbers of these two instabilities by the linear stability theory are critically compared with experimental and numerical results in the cross-slot channel flows.

\textbf{Saturday, November 23, 2019 4:40PM - 6:11PM – Session B34 Flow Instability: Boundary Layers Transition 616 - Tim Colonius, Caltech}

4:40PM B34.00001 Volume-Area and Area-Perimeter Dimensions of Turbulent-Spots Interfaces in Transitional Boundary-Layer Flow\textsuperscript{1}. ZHAO WU, TAMER ZAKI, CHARLES MEN-EVEAU, Johns Hopkins University — The nature of turbulent spots in transitional boundary layers, and whether their internal structure shares characteristics of equilibrium turbulence, remain open questions of considerable interest. Here we study scaling properties of the interface separating the spots from the outside flow. For high-Reynolds number turbulence, the outer interfaces are known to display fractal scaling with a fractal dimension near $D=2+1/3$, where the 1/3 can be related to the Kolmogorov scaling of velocity fluctuations (e.g. de Silva et al. PRL 2013). We measure the volume-area fractal scaling of the naturally triggered turbulent spots. The data are from the DNS of a transitional boundary layer available at the JHTDB (http://turbulence.pha.jhu.edu). The spot boundaries (interfaces) are determined without arbitrary threshold selection using an unsupervised machine learning method, namely the self-organizing map (Zhao et al. PRF 2019). Results from the volume-area fractal dimension confirm $D=7/3$, i.e. trends consistent with fully developed turbulence. Applying an alternative area-perimeter analysis on planar cuts at various heights shows D decreasing then increasing. It is argued that these trends could be associated to changes in the thickness of the interface at different heights from the wall.

\textsuperscript{1}National Science Foundation (grant \# OCE-1633124) and Office of Naval Research (grant No. N00014-17-1-2937).
4:53PM B34.00002 On the evolution of the velocity gradient in a minimal simulation unit of transitional boundary layers\textsuperscript{1} , AHMED ELNAHHAS, PERRY JOHNSON, ADRIAN LOZANO-DURAN, PARVIZ MOIN, Center for Turbulence Research, Stanford University | The transition of a boundary layer from laminar to turbulent state is associated with a rapid increase in friction and heat transfer coefficients and is accompanied by the rapid growth of velocity gradients throughout the boundary layer. This can be appreciated by visualizing isosurfaces of Q-criterion or other vortex identifiers and is particularly evident in late-stage transition when growing structures abruptly break down into more chaotic flow, generating turbulent spots. We consider the evolution of several velocity gradient invariants integrated in cross-stream planes using direct numerical simulations of canonical transition scenarios with minimal spanwise extent. The spanwise domain is restricted to fit only one wavelength of the oblique wave, leading to a single \( \Lambda \)-vortex being present at any streamwise location. The minimal unit simulation displays the main features of transition in larger domains, such as a realistic skin friction coefficient profile. The budget of the squared Frobenius norm of the velocity gradient tensor shows that the pressure term is orders of magnitude smaller compared to the source and sink terms. Furthermore, the profile of the Q-criterion squared exhibits a distinct plateau after the initial emergence of the hairpin vortex, and appears to be a good indicator of the onset of transition.

5:06PM B34.00003 Development for a Theoretical Model of Crossflow-induced Boundary-layer Transition\textsuperscript{1} , MAKOTO HIROTA, Institute of Fluid Science, Tohoku University, YUKI IDE, Japan Aerospace Exploration Agency, TAKAHISA HAYASHIDA, Graduate School of Information Sciences, Tohoku University, YUII HATTORI, Institute of Fluid Science, Tohoku University | On widely-used swept wings of aircrafts, laminar-turbulent transition of three-dimensional boundary layer mainly occurs through the process in which (i) a crossflow instability (referred to as the primary) first grows spatially and generates a vortex street and, then, (ii) the vortex street further induces low-speed streaks in the mainstream distribution that becomes unstable to a high-frequency secondary instability. Direct numerical simulation (DNS) can reproduce this process accurately, but the transition location sensitively depends on how the two kind of disturbance sources are fed to the primary and secondary instabilities, respectively. It is moreover difficult to understand the dependency on various flow parameters. In this study, we develop a theoretical model to estimate the growth rates of both the primary and secondary instabilities according to linear stability analyses. By noting a scale similarity to the Kelvin-Helmholtz instability, the inflection point and the shear profile of the flow enable us to estimate the growth rates. Our method is expected to be not only efficient to predict the transition location, but also useful for finding less unstable flow profiles that control devices should attain.

\textsuperscript{1}This work is based on results obtained from a project commissioned by the New Energy and Industrial Technology Development Organization (NEDO).

5:19PM B34.00004 Emergence of streaks and turbulent spots in an unsteady boundary layer beneath a solitary wave , ASIM ONDER, PHILIP LI-FAN LIU, National University of Singapore | Bypass route to transition is studied in a bottom boundary layer developing under solitary wave. First, the conditions for streak growth and breakdown are analyzed using a linear input-output framework and secondary stability analysis. Vortical perturbations whose intensity is about 1% of the maximum free-stream velocity are found to be sufficient to induce unstable streaks in moderate to high Reynolds numbers. In the second step, a natural bypass transition scenario is realized using direct numerical simulations, where a weak turbulent current is introduced to initiate the transition. The breakdown of streaks to turbulent spots is shown. Depending on their nucleation phase, the turbulent spots can grow to occupy the whole domain leading to a premature transition bypassing the emergence of two-dimensional modal instabilities.

5:32PM B34.00005 Linear and nonlinear dynamics of second-mode instability in hypersonic boundary layers (HBL)\textsuperscript{1} , UNNIKRISHNAN SASIDHARAN NAIR, DATTA GAITONDE, The Ohio State University | Hypersonic transition is often dominated by the second-mode instability. We perform a direct numerical simulation (DNS) informed by linear stability theory, to understand the eventual three-dimensional breakdown of this instability. Linear amplification and nonlinear saturation of this two-dimensional wave eventually culminate in the appearance of oblique waves, which break down the HBL into a turbulent state. A modal analysis of the transitional region identifies lambda-shaped vortices belonging to both fundamental and subharmonic categories. While the former appears relatively downstream, the subharmonic waves are observed immediately following nonlinear saturation. This nonlinear stage of transition is further analyzed through a novel unsteady flow perturbation (UFP) technique. UFP essentially tracks the linear evolution of perturbations on a nonlinearly saturated background flow, thus approximating a Floquet analysis for general configurations. UFP is shown to identify the most receptive superharmonic/subharmonic components in the periodically distorted flow. In addition to providing insights into the dynamics, relative to DNS, it provides an accurate low cost approximation of the breakdown spectrum in the early transitional stages.

5:45PM B34.00006 Nonlinear input-output analysis of laminar-turbulent transition for wall-bounded flows\textsuperscript{1} , GEORGIOS RIGAS, Imperial College London, DENIS SIPP, ONERA, TIM COLONIUS, Caltech | In a linear input-output analysis framework, the most amplified instabilities are typically described by considering singular vectors of the resolvent operator of the linearized Navier-Stokes equations. In this study, we extend the methodology to take into account nonlinear triadic interactions by considering a finite number of harmonics in the frequency domain using the Harmonic Balance Method. Optimal nonlinear forcing mechanisms that lead to transition and maximize the skin-friction coefficient are identified using direct-adjoint looping. We demonstrate the framework on a zero-pressure flat-plate boundary layer considering three-dimensional perturbations triggered by a few optimal forcing modes of finite amplitude. Depending on the frequency, spanwise wavenumber, amplitude and symmetries of the perturbation, we recover all the transition stages associated with K-type and H-type transition mechanisms, oblique waves, streaks, and their breakdown. The proposed frequency-domain framework identifies the worst-case frequency disturbances forwall-bounded laminar-turbulent transition.

5:58PM B34.00007 The Role of Fluctuating Dissipative Fluxes in the Receptivity of High-Speed Chemically Reacting Boundary Layers in Binary Mixtures to Kinetic Fluctuations

Asymptotic approximations are derived for the hydrodynamic force on a rigid, axisymmetric particle executing longitudinal or transverse oscillation in unsteady Stokes flow. The slender particle has an aspect ratio $a/L << 1$, where $L$ is the half-length of the particle, and $a$ is its characteristic cross-sectional width. The frequency of oscillation is parameterized by the complex quantity $\lambda^2 = -i\omega^2\nu/\nu$, where $\nu$ is kinematic viscosity, $\omega$ is particle oscillation frequency, and $i = \sqrt{-1}$. Asymptotic approximations for the force are obtained in three frequency regimes: (i) low frequency, $\lambda << 1$; (ii) moderate frequency, $\lambda \sim O(1)$; and (iii) high frequency, $\lambda >> 1$. Physical interpretations of the force in each regime are made and compared between the longitudinal and transverse oscillation cases. Our asymptotic predictions are in good agreement with the numerically computed frequency-dependent force on a prolate spheroid ($\epsilon = 0.1$) for longitudinal and transverse oscillations by Lawrence and Weinbaum (J. Fluid Mech., vol. 189, 1988) and Pozrikidis (Phys. Fluids, vol. 1, 1989), respectively.

4:53PM B35.00002 Rectified inertial forces in oscillatory flows: theory, simulation, experiment

Theory, simulation, and experiment show that inertial forces in oscillatory flows can rectify fluid motion, leading to effective flow rectification even in fluids where viscosity dominates. This phenomenon is important in a wide range of applications, from microfluidics to astrophysics. Theoretical predictions are confirmed through numerical simulations and experiments, highlighting the potential of oscillatory flows for flow control and propulsion in microscale devices.

5:06PM B35.00003 A simple and effect method for generating sub-kilohertz oscillatory flows in microchannels

By exploiting the physics of oscillatory flow, a simple and effective method for generating sub-kilohertz oscillatory flows in microchannels is developed. This method is applicable to a wide range of microfluidic devices and can be used for applications such as mixing, trapping, and propulsion in microscale systems.

5:19PM B35.00004 New insights into the migration patterns of a single capsule flowing in a pulsating microchannel

Using advanced imaging techniques, new insights into the migration patterns of a single capsule flowing in a pulsating microchannel are revealed. The results challenge traditional assumptions about capsule behavior and provide a deeper understanding of the complex dynamics involved in such systems.
Continuum breakdown of the acoustic field generated by a pulsating micro-sphere\(^1\), YARON BEN-AMI, AVSHALOM MANELA, Technion - Israel Institute of Technology — The flow field of a pulsating sphere is a canonical problem in acoustics. We consider the counterpart problem at small length scales of the sphere, where its radius is comparable with the gas mean free path. Such small scales are often encountered in the process of time-resolved spectroscopy of micro-particles. At these conditions, the gas rarefaction effects become important and the continuum description breaks down. The acoustic field is analyzed in the entire range of sphere length-scales. Numerical calculations are carried out via the direct simulation Monte Carlo method; analytical predictions are obtained in the free-molecular and near-continuum regimes. In the latter, the regularized thirteen moments model is applied, to capture the system response at states where the Navier-Stokes-Fourier equations break down. The results quantitate the dampening effect of gas rarefaction on the acoustic field. At near-continuum conditions, the acoustic field is composed of exponentially decaying ‘compression’, ‘thermal’ and ‘Knudsen-layer’ modes, reflecting thermoviscous and higher-order rarefaction effects. Stronger attenuation is obtained in the free-molecular regime, where boundary sphericity results in a geometric reduction of the molecular layer affected by the source.

Application of Nonlinear Electrokinetic Transport using Network Heterogeneity of Porous Media\(^1\), HYEKYUNG LEE, Seoul National University, ALI MANI, Stanford University, SUNG JAE KIM, Seoul National University — Nanoscale electrokinetic transport through perm-selective membranes has been actively researched using a micro/nanofluidic platform recently. The ion depletion layer formed near the membrane under dc bias can be compartmentalized using heterogeneous microchannels and a numerical/experimental study using the simplified porous media demonstrated an internal recirculation flow due to different hydraulic resistance in network of channels. Furthermore, overlimiting current significantly increased due to this flow so that the channel with the higher resistance played as the main current path. In this presentation, we applied this mechanism to practical engineering problems. First, we investigated electrokinetics by laying a permselective membrane on only the main current path. By comparing the devices either with uniformly patterned membrane vs non-uniformly patterned membrane (i.e. membrane only at the current paths), a similar perm-selective ion transportation was measured, leading to the same mass transfer but the half of membrane material cost. Second, it is expected that network effect could localize the membrane fouling because the mass transfer is dominant through the main current path.

Capacitive Charging of Multi-ion Electrolytes confined in parallel electrodes\(^1\), YUN SUNG PARK, IN SEOK KANG, Department of Chemical Engineering, POSTECH — Charging and discharging of ionic devices have been widely studied theoretically and experimentally. Especially, numerous kinds of electrolytes and their combinations have been utilized in order to enhance capacitances or frequency dependencies of the devices. However, the theoretical studies of effects of multiple ions on the properties of the devices are insufficient. In this work, we study the effect of multiple ions quantitatively using continuum approach. Electrolytes are confined in one-dimensional parallel electrodes, which is simplest system for many ionic devices. The multiple ions with different sizes and valences are chosen and their effects are compared along with the sparse and dense bulk concentrations. We focus on both the equilibrium distributions and the dynamic behaviors of ions, which are related to capacitances and frequency dependencies, respectively. The quantitative analyses are done numerically by dividing charge densities and fluxes of individual ions. Lastly, simple electroosmotic flows are calculated from the obtained charge densities.

Negative Pressure of Ionic Liquids Inside a Nanoslit: Molecular Dynamics Study\(^1\), YU DONG YANG, JUNG MIN OH, IN SEOK KANG, POSTECH — Predicting the force the acting on the charged surface is important to prevent deformation or swelling of pores. When the electrostatic interaction between charged pore and its counter-ions is predominant, the internal electrolyte can pull the wall. This means the total pressure becomes negative. Since it becomes complicated to predict with considering the large size and complex shape of ionic liquids, molecular dynamics simulations are conducted to analyze the pressure acting on the nanoslit wall. The pressure change with respect to the slit width under 1 nm scale was analyzed using coarse-grained model, and it is determined by the competition between the contact and electrostatic component of the total pressure. When the slit width is below a double of each ion size, the negative pressure scale is about \(10^3\) atm and it is 20 to 40 times the bulk osmotic pressure of each ionic liquids. The ion shape or size is related to the magnitude of contact component, but it hardly affects the negative pressure when the electrostatic component is dominant due to the ion re-arrangement in a slit.

5:19PM B36.00004 Understanding the electrokinetic interaction between dynamically tunable nanofluidic channels connected in series. BARAK SABBAGH, Technion - Israel Institute of Technology, ELAD STOLOVIC, Harvard University, GILAD YOSSIFON, Technion - Israel Institute of Technology. The passage of an electric current through a permselective medium results in a phenomenon known as concentration polarization (CP). This phenomenon has been the focus of intense research, particularly regarding its relationship with microfluidic applications, e.g., on-chip desalination and enhanced biosensing sensitivity. These effects have been observed in a fixed geometry and properties of the permselective medium (i.e., nanochannel) which defines the location, intensity, and length of the CP layer. The ability to dynamically tune the geometry of the permselective medium allows us to optimize existing processes and open up new application possibilities. This is realized using pneumatically controlled microvalves where the formed gap between the elastically deformed membrane, which is controlled by external pressure chamber, and the nanochannel, forms the ion permselective nanochannel. In contrast to previous studies of such a system, here we extend this approach to several individually addressable microchannels that are connected in series within the same microchannel. Such interaction between two or more dynamically formed nanochannels yields interesting results of both the transient and steady-state behavior of the CP layers and related electrical response.

5:32PM B36.00005 Revisiting, resolving and unifying the nanochannel-microchannel electrical resistance paradigm. RAMADAN ABU-RJAL, RAN ESHEL, Technion-Israel Institute of Technology, YOAV GREEN, Ben-Gurion University of the Negev. Until recently, the accepted paradigm was that of Ohmic electrical response of nanochannel-microchannel systems determined solely by the nanochannel while the effects of the adjacent microchannels are negligible. Two, almost identical, models were suggested to rationalize experimental observations that appeared to confirm the paradigm. However, recent works have challenged this paradigm and showed it to be incorrect, namely, the microchannels contribute in a non-negligible manner. Two newer nanochannel-microchannel models were suggested to replace the nanochannel-only models. These models were asymptotic solutions limited to either very low or very high concentrations. Here, we review these four leading models. The most popular is shown to be incorrect, while the remaining models are unified under a newly derived solution which shows remarkable correspondence to simulations and experiments. The unifying model can be used to improve the design of any nanofluidic based systems as the physics are more transparent, and the need for complicated time-consuming preliminary simulations and experiments has been eliminated.

5:45PM B36.00006 Enhanced Electrokinetic Energy Conversion & Ion-Selective Transport in Macroscopic Vertically Aligned BNNT Membranes. SEMIH CETINDAG, Rutgers University, AADITYA PENDSE, University of Illinois, Chicago, ROBERT F. PRAINO, Chasm Advanced Materials, SANGIL KIM, University of Illinois, Chicago, JERRY W. SHAN, Rutgers University. Recent nanofluidic experiments with single or few nanopenes in graphene, MoS2, and h-BN have shown unique fluidic transport properties and the potential for electrokinetic energy conversion with unprecedented power densities. In such nanopenes, the high-surface charge makes possible a diffusio-osmotic mechanism for ion-selective transport, distinct from the Donnan exclusion in the conventional membranes. Here, we describe the fabrication of the first-ever macroscopic vertically aligned boron-nitride nanotube (VA-BNNT) membranes, and our study of their ion-selectivity mechanisms and osmotic-power-generation performance. We show that the VA-BNNT membranes are highly cation-selective even when the Debye length is smaller than the inner-pore radius of the nanotubes. Moreover, the membranes exhibit osmotic-energy-conversion efficiencies of 30%, and have osmotic power densities (based on open pore area) comparable to and even exceeding that of single BNNTs, up to 7,500 W/m² at pH 11 for a 1M:1mM KCl molarity difference. This osmotic power density increase with increasing surface-charge density at higher pH, but remain substantial even at pH 7. To further elucidate the mechanism(s) for the ion selectivity, we compare the power generation and transport rates of the VA-BNNT membranes for salts having different cation and anion diffusivities and thus diffusio-osmotic parameters.

Session B37 Turbulence: Particle Laden Flows

4:40PM B37.00001 Effect of fluid inertia on the orientation of a small spheroid settling in turbulence. BERNHARD MEHLIG, University of Gothenburg. We study the angular dynamics of small non-spherical particles settling in a turbulent flow. Most solid particles encountered in Nature are not spherical, and their orientations affect their settling speeds, as well as their collision and aggregation rates in suspensions. Whereas the random action of turbulent eddies favors an isotropic distribution of orientations, gravitational settling breaks the rotational symmetry. We demonstrate here that the fluid-inertia torque plays a dominant role in the problem. As a consequence rod-like particles tend to settle horizontally in turbulence, the more so the larger the settling number $S_v$ (a dimensionless measure of the settling speed). For large $S_v$ we determine the fluctuations around this preferential horizontal orientation for prolate particles with arbitrary aspect ratios, assuming small Stokes number $St$ (a dimensionless measure of particle inertia). This overdamped theory predicts that the orientation distribution is very narrow at large $S_v$, with a variance proportional to $S_v^{-1/4}$ for rods and $S_v^{-9/8}$ for disks. The abstract is based mainly on arXiv:1904.00481 (New Journal of Physics https://doi.org/10.1088/1367-2630/ab3062).

KAW 2014.0048, VR grant no. 2017-3865, IDEXLYON project (Contract ANR-16-IDEX-0005) under University of Lyon auspices. Computational resources were provided by C2S2 and SNIC, and PSA2.

4:53PM B37.00002 Collision efficiency of rapidly settling particles in a turbulent flow. PIJUSH PATRA, ANUBHAB ROY, Department of Applied Mechanics, Indian Institute of Technology Madras, Chennai 600036, India, DONALD L. KOCH, Smith School of Chemical and Biomolecular Engineering, Cornell University, Ithaca, NY 14853, USA. We calculate the collision rate constant of hydrodynamically interacting low-sphericity spherical particle pairs sedimenting in a homogeneous isotropic turbulent flow in the rapid settling limit where the settling rate appears well described by the Kolmogorov eddy size. The result is expressed in terms of the velocity gradient auto-correlation function along the settling trajectory and in this particular problem due to rapid settling assumption we are able to relate it with the turbulence energy spectrum. A convection-diffusion equation for pair probability density function, $P(r,t)$, is derived in terms of the hydrodynamic turbulent pair diffusion and drift and then solved numerically to calculate the collision rate constant.
5:06PM B37.00003 Measurement of Inertial Particle Collision Statistics in Isotropic Turbulence Using 3D Particle Tracking Velocimetry¹. ADAM HAMMOND, ZACH LIANG, HUI MENG, University at Buffalo SUNY — We experimentally investigate the effects of turbulence and particle inertia on three particle collision statistics in particle-laden isotropic turbulence: radial distribution function (RDF), radial particle-pair relative velocity (RV), and for the first time, geometric collision kernel for which RDF and RV are factors. Experimentally obtaining these statistics has been difficult in the past especially as particle separation distance decreases below the Kolmogorov length scale $\eta$ to near-contact, where the physics becomes obscure and theoretical models may not hold. Using Shake-the-Box 3D particle tracking, we are able to resolve particle positions and velocities at $r \leq \eta$, which enables estimations of RDF and RV. Experiments are performed in a near-contact condition and compared to the colliion kernel. Experimental results are compared to previously calculated collision kernels for which RDF and RV are factors. RDF increases as $r/\eta$ decreases to 0.01, and increases with $St$. RV decreases as $r/\eta$ increases until $r/\eta = 1$, recapitulating previous DNS and experimental results (Dou et al., 2018, DOI: 10.1017/jfm.2017.813); however, as $r/\eta < 1$, RV exhibits a sharp upturn. This first simultaneous near-contact estimation of RDF, RV, and collision kernel calculated from real turbulence enables examination of theory and DNS, and may reveal new phenomena not previously accounted for in prior models.

5:19PM B37.00004 Fall velocities of Hydrometeors in Turbulent Flow¹. AHMAD TALAEI, TIM GARRETT, University of Utah — An understanding of the interactions of precipitating aerosols, droplets and ice crystals within an atmospheric turbulent flow is fundamental to predictions of atmospheric weather and climate. Here we examine the mean settling velocity of a hydrometeor falling into a random Gaussian turbulent flow using hydrometeor images and velocities captured by the Multi-Angle Snowflake Camera (MASC) at Oliktok Point, Alaska. Analyses reveal hydrometeor Reynolds numbers ranging from 1 to 1000, sharply peaked at 200. Due to mathematical difficulties, previous analytical solutions of the equation of motion of a falling sphere in a viscous liquid have been constrained to the slowly falling particles in the Stokes regime with Reynolds numbers less than unity. In this study, we introduce an analytical solution for higher Reynolds numbers and develop an equation of motion for studying the interaction of atmospheric turbulence and hydrometers. The results show settling velocity reduction in weak turbulence and enhancement in strong turbulence.

¹The research is granted by Department of Energy Atmospheric System Research Award No. DE-SC001282

5:32PM B37.00005 Inertial particle velocity and distribution in vertical turbulent channel flow: a numerical and experimental comparison¹. DAVID RICHTER, GUIQUAN WANG, University of Notre Dame, KEE ONN FONG, FILIPPO COLETTI, University of Minnesota, JESSE CAPECELATRO, University of Michigan — This study is concerned with the statistics of vertical turbulent channel flow laden with inertial particles for two different volume concentrations ($\Phi_V = 3 \times 10^{-6}$ and $\Phi_V = 5 \times 10^{-5}$) at a Stokes number of $St = 58.6$ based on viscous units. Two independent direct numerical simulation (DNS) models utilizing the point-particle approach are compared to recent experimental measurements, where all relevant nondimensional parameters are directly matched. While both numerical models are built on the same general approach, details of the implementations are different. At low volume loading, both numerical models are in general agreement with the experimental measurements, with certain exceptions near the walls. At high loading, these discrepancies are increased, and it is found that particle clustering is overpredicted in the simulations as compared to the experimental observations. Potential reasons for the discrepancies are discussed. As this study is among the first to perform one-to-one comparisons of particle-laden flow statistics between numerical models and experiments, it suggests that continued efforts are required to reconcile differences between the observed behavior and numerical predictions.

5:45PM B37.00006 Simultaneous tracking of suspended particles and time-resolved PIV in a turbulent boundary layer¹. FILIPPO COLETTI, LUCIA BAKER, University of Minnesota — A detailed picture of the interaction between suspended sediment and the carrier fluid has only recently begun to emerge due to recent advances in experimental and numerical methods. Here we investigate experimentally the dynamics of spherical particles in a turbulent boundary layer in a saltation-suspension transport regime. Particle image velocimetry and particle tracking velocimetry are used to obtain simultaneous, time-resolved fluid velocity fields and particle trajectories. Statistics of particle velocity, particle acceleration, and fluid velocity at particle locations are computed to characterize particle behavior and investigate mechanisms for particle deposition and resuspension. Fluid ejection events near the wall appear to be a main mechanism for particle suspension, while fluid sweeps contribute less to particle deposition. Particle acceleration variance is found to peak markedly near the wall, in response to passing turbulent structures. Resuspension is triggered by an increase in streamwise fluid velocity at particle location, while deposition is preceded by a decrease in fluid velocity. Resuspending particles experience much stronger wall-normal acceleration magnitude than depositing particles.

5:58PM B37.00007 Shape- and scale-dependent coupling between inertialless spheroids and velocity gradients in turbulence. NIMISH PUJARA, University of Wisconsin - Madison, CRISTIAN LALESCU, MICHAEL WILCZEK, Max Planck Institute for Dynamics and Self-Organization — Particles of different shapes and sizes are commonly found suspended in a turbulent flow in the environment and in industrial processes. To better understand the dynamics of neutrally-buoyant, non-spherical particles in dilute concentrations, we compute the motion of inertialless spheroids in direct numerical simulations of turbulence using one-way forcing. Particles of different sizes are modelled as tracer bubbles after the velocity field has been coarse-grained at different filter scales. The focus is on the statistics of particle rotations and what they reveal about the interaction between the particles and velocity gradients. While particle rotations in the co-ordinate axes fixed to each particle show interesting variations with particle shape and filter scale, the mean-square value of particle angular velocity in the global co-ordinate axes is nearly constant across all shapes and scales. These trends are further probed by examining the particle alignment with fluid vorticity and how this depends on particle shape and filter scale. Finally, a comparison between these results and laboratory experiments provides insights into how particle inertia may influence particle-turbulence coupling for large, anisotropic particles.

Saturday, November 23, 2019 4:40PM - 6:11PM – Session B38 Porous Media Flow CO2 Sequestration and Dispersion 620 - Kenneth T. Christensen, University of Notre Dame
4:40PM B38.00001 CO₂ sequestration via pressure driven displacement on fluid-gas plugs in a capillary tube. SRAVYA SASETTY, THOMAS WARD, Iowa State University — This talk focuses on experiments conducted to further our understanding on the feasibility of carbon sequestration using a chemical reaction between CO₂ gas and aqueous Ca(OH)₂, which produces CaCO₃ precipitates. Experiments were performed in a capillary tube (dia ≈ 800 µm) by displacing liquid plugs of different volumes containing Ca(OH)₂ (0 ≤ c ≤ 20 mol m⁻³) dissolved in aqueous glycerol solution using CO₂ gas at pressures 0.2 psig ≤ P ≤ 1.0 psig. A CCD camera captured the displaced and displacing fluid interfaces and an in-house MATLAB code was used to measure both the mean Uₘ and tip Uₜ velocities. Subsequently, we measure the film thickness using the expression m = 1 − Uₘ/Uₜ where m is a measure of displaced fluid still remaining inside the tube. Surface tension values obtained using an in-house pendant drop tensiometer were used to calculate the capillary number Ca. We report the m versus Ca trends observed in our experiments and compare them against immiscible fluid displacement classical results.

4:53PM B38.00002 Resolving the pore-scale dynamics of multiphase flow of supercritical CO₂ and water in a 2D circular porous micromodel using high-speed microscopic PIV. YAOFA LI, GIANLUCA BLOIS, KENNETH CHRISTENSEN, University of Notre Dame — Multiphase flow of supercritical CO₂ and water in porous media is relevant to geologic carbon sequestration and enhanced oil recovery, among many other applications in the energy and environmental sectors. After nearly two decades of research, it is now apparent that many macroscopic flow behaviors are controlled by pore-scale physics down to the micrometer scale. Recent evidence suggested that transient flow events such as Haines jumps, occurring on the time scale of milliseconds, and the associated dynamic effects, can greatly influence the accuracy of predictive models if not accounted for. Moreover, wetting properties of the porous matrix pose a strong control on the observed physics and dynamics, thus challenging its microscopic and macroscopic descriptions. To this end, the pore-scale flow of water and CO₂ is quantified using high-speed micro-PIV under reservoir-relevant conditions in a 2D circular micromodel featuring randomly distributed pillars and variable wettability. Resolving the flow is enabled by the very high temporal and spatial resolutions of the measurements. Statistical analysis during both steady and transient flows is performed to gain further insight into the intermittent behaviors as well as to quantify the effects of wettability on such behaviors.

5:06PM B38.00003 Dispersive entrainment in gravity currents in layered porous media. CHUNENDRA K. SAHU, JEROME A. NEUFELD, University of Cambridge — We present experimental results to quantify mixing in gravity currents in layered porous media occurring due to dispersion between dense and light fluids. Dye-attenuation based laboratory experiments were performed in homogeneous medium and heterogeneous medium consisting of two or four layers of distinct permeabilities. These experimental results show that the effects of mixing are more prominent closer to the nose and less prevalent towards the source location. In layered media, the volume of entrainment is much higher than that in the homogeneous medium due to flow instabilities like over-riding and Rayleigh-Taylor instabilities, which result in higher mixing rates. These experimental results motivate a general mathematical model in which we exploit the large aspect ratio of these currents to formulate a depth-averaged model of the evolution of the mass and buoyancy. We assume that the entrainment of ambient fluid into the gravity current can be parameterised by the mean horizontal velocity and an entrainment coefficient. Based on our experimental measurements, we quantify the dependence of the dispersive entrainment on the number of layers and their permeabilities.

5:19PM B38.00004 Some effects of cross-bedding on tracer dispersion in porous formations. NEERAJA BHAMIDIPATI, ANDREW WOODS, University of Cambridge — The sequential deposition of sediment in fluvial settings often leads to structures known as cross-bedding, in which the geological strata are aligned at an angle to the horizontal and consist of alternating interbedded layers of fine and course sediment. This leads to anisotropy in the permeability, which tends to be substantially higher in the along-bed direction. Over time, many such layers build up leading to highly heterogeneous permeable rocks. Many such formations have relatively higher permeability and can be ideal candidates for carbon sequestration or may be involved in the subsurface hydrological system, and so there is considerable interest in the flow patterns which arise through such formations. We present a series of numerical calculations of the spreading of a pulse of tracer through such formations, based on the pattern of such heterogeneity from a number of rock outcrops. We analyse these observations and develop some low order models of the controls on the dispersion and spreading of a cloud of tracer as it moves downstream. Our models have relevance for interpretation of tracer tests for groundwater flows and also in interpreting patterns of flow during carbon sequestration.

5:32PM B38.00005 Dissolution-driven convection of partially miscible fluids in porous media¹. CHING-YAO CHEN, National Chiao Tung University, QIAN LI, WEI HUA CAI, Harbin Institute of Technology, ECKART MEIBURG, UC Santa Barbara — Dissolution-driven convection produced at a free interface between CO₂ and brine in porous media is numerically studied to mimic the complex diffusion and flow process in the geological sequestration of CO₂. A Darcy-Cahn-Hilliard model with a particular free energy distribution is employed to simulate the partially miscible feature between the CO₂ and the brine. Simulations reveal that the evolution of the CO₂ plume exhibits several distinct stages, such as triggering, growing, merging and damping. Consequently, for the temporal development of the solute flux we can distinguish three major time periods, such as free convection, constrained convection and shutdown. In the free convection period, the time-averaged solute flux decreases with Rayleigh number. On the other hand, the solute flux is independent of the Rayleigh number in the periods of constrained convection and shutdown. Correlations of the solute flux and the Rayleigh number are proposed based on the simulations, which are able to predict the solute flux and the dissolved quantity of CO₂ into brine.

5:45PM B38.00006 Modeling solutal convection in porous media: from pore to Darcy scale. MARC HESSE, BAOLE WEN, Department of Geological Sciences, The University of Texas at Austin, SAHAR BAKHSHIAN, SEYYED HOSSEINI, Bureau of Economic Geology, The University of Texas at Austin — We model the transport process of convective carbon dioxide dissolution in porous media on both pore and Darcy scales. Numerical simulations of the Navier-Stokes equations are performed in two-dimensional granular packing with constant porosity. We vary the driving force by changing the grain/pore size and the density difference to explore the effect of mechanical dispersion on the convective pattern and flux. We upscale the problem and then perform the Darcy-scale simulations with Fickian mechanical dispersion. The Darcy model reproduces both the trend in the convective pattern and quantitative fluxes of the pore-scale results, via adjusting the longitudinal dispersivity and the anisotropy of mechanical dispersion. Our simulations show the flux recovers a linear scaling with reduced coefficient as dispersion becomes dominant, consistent with the recent laboratory experiments. However, sub-linear flux scaling arises either in a transitional regime where diffusion and dispersion are comparable or if grains become too coarse. In this case, the pore-scale simulations show that convective up- and downwellings arise in two-dual pores. This leads to additional mixing not accounted for in Fickian dispersion model on the Darcy scale. The buoyancy-driven pore-scale mixing observed elsewhere has different characteristics from mixing processes in pressure-driven flows and requires a new approach to upscale them to the Darcy scale.
5:58PM B38.00007 The effect of non-uniform poroelastic reservoir geometry on the propagation of a buoyant gravity current. ADAM BUTLER, ALEX COPLEY, JEROME NEUFELD, University of Cambridge — Gravity currents in confined porous media occur in a variety of geological settings, with CO$_2$ storage one of particular current importance. How the CO$_2$ current and the porous medium develop over time is sensitive in particular to the pressure in the ambient fluid. This is set by compressibility and poroelastic deformation of the porous medium, and in this manner the current may experience the complex geometry of the domain. Here we model the flow of a gravity current injected into such a porous medium, exploiting the aspect ratio of a typical aquifer in order to vertically average the flow and medium properties across the domain. We derive coupled advection-diffusion equations for the injected and ambient phases and focus on the ambient phase in the limit of large Young’s modulus. Using a simple elastic-layer model, we incorporate the response to deformation from the overburden and calculate the diffusion of pore pressure away from the injection point as well as the resulting deformation transmitted to the surface. As a specific case study, we apply our model to an aquifer with converging lid and basement in order to investigate the effect of non-uniform reservoir geometry on propagation.

8:00PM B40.00001 Meet the Physical Review Journal Editors Reception (8:00pm - 10:00pm) —

Sunday, November 24, 2019 8:00AM - 10:10AM — Session C01 Turbulent and Chemically-reacting Flow Modeling I 2A - Peyman Givi, University of Pittsburgh

8:00AM C01.00001 Edward E. O’Brien’s Seminal Contributions to Turbulence Theory, FOLUSO LADEINDE, Stony Brook University, CESAR DOPAZO, Universidad Zaragoza, PEYMAN GIVI, University of Pittsburgh — A brief overview will be presented of the influential contributions of Edward E. (Ted) O’Brien to the theory of turbulence, with an emphasis on scalar mixing and reaction. While perhaps best known for his work on the transported PDF methods, Ted’s contributions are very diverse and consider a broad range of theoretical and computational approaches. In the 1960s, he made some very fundamental contributions to the spectral theory of reactive scalars, analyzed the consequences of passive scalar tagging using Corsin’s “backward Lagrangian diffusion” concept, and contributed to the interpretation of Kraichnan’s “direct interaction approximation” (DIA) for turbulent mixing. In the 1970s-1980s, he focused on scalar PDF Functional and Function methods. In fact, he is widely recognized for introducing and popularizing single- and multi-point PDF closures, as well as the scalar-gradient PDF within the reactive turbulent flow community. In the 1990s, he focused on applying the EDM and the “amplitude mapping closure” (AMC) models, respectively to reactive turbulent scalars and mixing. With wider availability of supercomputers in the late 1990’s-2000’s, Ted utilized DNS for the development and appraisal of modern turbulence closures. He is also credited with introducing the “filtered density function” (FDF) transport equation for LES of turbulent reactive flows. In fact, he is the first to develop a transported scalar-FDF equation for multi-species turbulent reactive flows. Professor O’Brien’s publications continue to be highly cited within the turbulence research community.

8:13AM C01.00002 Numerical Simulation of Colorless Distributed Combustion with LES/FMDF, HUSAM ABDULRAHMAN, FARHAD JABERI, Michigan State University, ABDOULAHAD VALIDI, ANSYS Inc., ASHWANI GUPTA, University Of Maryland — Honoring Ted O’Brien. Turbulent mixing and combustion in non-premixed and premixed Colorless Distributed Combustion (CDC) systems are studied with the hybrid large eddy simulation/filtered mass density function (LES/FMDF) methodology and its Eulerian–Lagrangian computational solver. The CDC has shown to significantly reduce NOx and hydrocarbon emissions while improving the reaction pattern factor and stability with low pressure drop and noise. The combustion in CDC is distributed and is characterized by wide fluctuations in flow variables. In addition to non-conventional distributed turbulent reaction, mixing between fuel, oxidizer, and combustion products in CDC is unique and complex. The LES/FMDF model is shown to be able to capture all the unique features of turbulent mixing and combustion in CDC. The consistency of the Eulerian and Lagrangian parts of LES/FMDF is established for both non-reacting and reacting conditions. The LES/FMDF results are shown to be in good agreement with the available experimental data. The numerical results indicate that the variations in the inflow air temperature, jet velocity and composition and premixing have a significant effect on the flow, mixing and combustion in the CDC. They also indicate the importance of jets setup in the combustor.

8:26AM C01.00003 Filtered Mass Density Function for Large-Eddy Simulations of Multiphase Turbulent Reacting Flows, FARHAD JABERI, Michigan State University, ZHAORUI LI, Texas A&M University-Corpus Christi, ARAZ BANAEEZADEH, Altair Engineering Inc., ABOLFZAL IRANNEJAD, Alcon-Novartis Inc. — Honoring Ted O’Brien. The filtered mass density function (FMDF) methodology is further extended and employed for large-eddy simulations (LES) of multiphase turbulent reacting flows. The two-phase LES/FMDF model is implemented with a unique Lagrangian-Eulerian-Lagrangian mathematical/computational methodology. In this methodology, the filtered carrier gas velocity field is obtained by solving the filtered form of the compressible Navier-Stokes equations while the gas scalar (e.g., temperature and species mass fractions) field and the liquid (spray) phase are obtained by solving two different sets of Lagrangian equations. The two-way interactions between the phases and all the Eulerian and Lagrangian fields are included in the two-phase LES/FMDF methodology. The accuracy and reliability of the model is demonstrated by comparing the two-phase LES/FMDF results with those obtained from the direct numerical simulation (DNS) and experimental data for a range of fundamental and practical multiphase flows including a spatially developing turbulent mixing layer with evaporating and reacting droplets and spray combustion in a preheated high-pressure closed chamber, a dump combustor, a double-swirl burner, and an internal combustion engine.
8:39AM C01.00004 A High-Order FDF Large Eddy Simulator of Complex Flows .
SHERVIN SAMMAK, Center for Research Computing, University of Pittsburgh, AIDYN AÎTZHAN, ARASH NOURI, PEYMAN GIVI, Department of Mechanical Engineering and Materials Science, University of Pittsburgh — Honoring Ted O’Brien. The flow solvers in most previous LES-FDF are based either on high-order discretization schemes in simple flows, or low-order (finite-volume) methods in complex flows. In this work, we develop a new computational methodology which allows LES of complex flows via the use of a high-order spectral-hp element scheme. The high order accuracy of the spectral discretization and the versatility of the finite element domain decomposition, facilitate high-fidelity simulation of flows within complex geometries. This CFD solver is combined with a Lagrangian Monte Carlo scheme for LES of a bluff-body reacting flow via the FDF subgrid scale closure [1]. Demonstrations are made of the consistency and the overall superior performance of this high order hybrid scheme. [1] Gao, F. and O’Brien, E. E., “A Large-Eddy Simulation Scheme for Turbulent Reacting Flows,” Phys. Fluids A, vol. 5(6), pp. 1282-1284 (1993).

8:52AM C01.00005 On Large Eddy Simulation/Filtered Density Function based Modeling of Circular Bluff Body Configurations . CESAR CELIS, RICARDO FRANCO, Pontificia Universidad Catolica del Peru (PUCP) — Honoring Ted O’Brien. Large eddy simulation/filtered density function (LES/FDF) numerical results of inert and reacting flows characterizing the near wake of bluff body configurations are discussed in this work. Circular bluff body configurations are studied because they feature strong interactions between turbulence and chemical reaction, as well as pollutants formation. All numerical results obtained here are compared to experimental data gathered previously. Parameters particularly analyzed include velocity profiles, turbulent kinetic energy, Reynolds stress and strain rate tensors. A strong anisotropic flow is observed from the obtained results along with a flow recirculation zone consisting of a toroidal vortex. At inert conditions, large turbulent fluctuations are found at the stagnation point region. The observed flow anisotropy is associated with the stagnation point flow. The results discussed here correspond to on-going work involving both bluff body burner configurations and numerical predictions of rather complex phenomena such as soot formation.

9:05AM C01.00006 Molecular mixing in highly turbulent premixed flames1, XINYU ZHAO, PATRICK MEACHER, University of Connecticut — Honoring Ted OBrien. The molecular mixing rules and rates in premixed flames subject to intense turbulence are investigated in this study. Direct numerical simulation (DNS) of a spherical product kernel is conducted in a homogeneous isotropic turbulence box. The triply periodic computational domain outside the product kernel is comprised of fresh mixtures. The transient flame kernel undergoes flame propagation, local extinction, and eventually global extinction. During the transition, the compositional space evolves from a low-dimensional manifold to increasingly higher dimensions. The DNS data are subsequently explicitly filtered to study the subgrid-scale behavior of the scalars. The Euclidean minimum spanning trees are constructed to understand the change of localness during the extinction process. Conditional statistics of major and minor species are collected, according to the mixing rules of various mixing models. A scalar gradient based mixing frequency model is constructed and assessed for its suitability to represent the mixing rates of critical species during all phases of the flame kernel evolution.

9:18AM C01.00007 Uniform mean scalar gradient in grid turbulence: Asymptotic probability distribution of a passive scalar , XIAODAN CAI, United Technologies Research Center — Honoring Ted O’Brien. Dr. Edward E. O’Brien was my Ph.D advisor in mechanical engineering at Stony Brook University. It was he who introduced me to study flow turbulence in the United States after we met at a Fluid Dynamics conference in Beijing. He was an extremely humble, patient and optimistic person, and was an inspiration to all. Dr. O’Brien stressed the importance of understanding the fundamentals and was rigorous in applying them to solve important problems. I am one of Professor O’Brien’s students who has benifited immensely from his approaches and values. I will now present our work on asymptotic behaviors of probability distribution for a passive scale in grid turbulence, which highlights Professor O’Brien’s legacy.

9:31AM C01.00008 Modeling Radiative Heat Transfer and Turbulence-Radiation Interactions Using PDF and FDF Methods , DANIEL HAWORTH, The Pennsylvania State University — Honoring Ted OBrien. In 1974, Dopazo and O'Brien proposed using a modeled equation for the probability density function of a set of scalar variables that describe the thermochemical state of a reacting medium (a transported composition joint PDF) to model mixing and reaction in chemically reacting turbulent flows. Since then, the benefits of PDF methods, including subsequent extension to large-eddy simulations (filtered density function (FDF) methods), for modeling turbulence-chemistry interactions have been well established. Those benefits are a consequence of the ability of PDF/FDF methods to represent the influences of unresolved turbulent fluctuations on one-point physical processes (such as chemical reactions) in a natural way. For the same reason, PDF/FDF methods have an advantage in dealing with the influences of unresolved turbulent fluctuations on radiative emission. And when coupled with a stochastic radiation solver, the benefits can be extended to radiative absorption, thereby capturing both emission and absorption turbulence-radiation interactions. A model that combines stochastic Lagrangian particle PDF/FDF methods and a photon Monte Carlo method for radiative transfer is presented. Results are presented for laboratory flames and high-pressure combustion systems.

Presentations:

**Investigation of scalar-scalar-gradient filtered joint density function for large eddy simulation of turbulent combustion**

9:57AM C01.00010 Investigation of scalar-scalar-gradient filtered joint density function for large eddy simulation of turbulent combustion

CHENNING TONG, Clemson University — Honoring Ted O’Brien. The scalar-scalar-gradient filtered joint density function (FJDF) is studied experimentally. Measurements are made in the fully developed region of an axisymmetric turbulent jet (with a jet Reynolds number of 40000) using an array consisting of three X-wires and three resistance-wire temperature probes. Filtering in the cross-stream and streamwise directions are realized by using the array and by invoking Taylor’s hypothesis, respectively. The measured mean FJDF conditional on the (subgrid-scale) SGS scalar variance is unimodal when the SGS scalar variance is small compared to its mean. The scalar gradient depends weakly on the SGS scalar. For large SGS variance the FJDF is bimodal and the gradient depends strongly on the SGS scalar. The SGS scalar under such a condition contains diffusion layer structures and the SGS mixing is similar to the early stages of binary mixing. The iso-scalar surface in the diffusion layer has a lower surface-to-volume ratio than those in a well mixed scalar. The conditionally filtered diffusion of the scalar gradient has a S-shaped dependence on the scalar gradient, which is expected to be qualitatively different from that of a reacting scalar under fast chemistry conditions. However, because modeling is performed at a higher level and because the scalar-scalar-gradient FJDF contains the information about the scalar dissipation and the surface-to-volume ratio, the FJDF approach is expected to be more accurate than scalar filtered density function approaches and has the potential to model turbulent combustion over a wide range of Damkohler numbers.

**Progress and Challenges for Computational Naval Hydrodynamics**

8:00AM C02.00001 Physics of Naval Flows

THOMAS FU, Office of Naval Research — The flow past a ship operating in the ocean is one of our most challenging physics problems. Looking at a ship operating in waves, we see a fluid sheet separating off the bow, a multiphase contact line along the hull waterline, spray and bubbles from wave breaking, air wakes, and Kelvin ship waves. Below the waterline, we see turbulent boundary layers, D-3 flow separation and vortices, cavitation, and the rotational flow from the propeller. We also have the ocean itself adding a layer of complexity. A marine platform interacts with the world through environmental and hydrodynamic forcing. The environment (waves, wind, and buoyancy/gravity) acts on the platform, and it acts on the environment (propulsor, hull, and control surfaces). However, a naval platform’s performance is characterized by more than just its performance as a ship, and in fact, it might be a submarine, planning craft, or amphibious vehicle, and the performance is also now characterized by its ability to perform military missions and survive. To the list of technical areas we have already mentioned, fluid dynamics and oceanography, we can now add acoustics, heat transfer, and meteorology. As we have noted the complexity of naval flows due to the range of physical phenomena (turbulence, waves, wave breaking, cavitation, boundary layers, etc.), we should also note the complexity due to the range of spatial and temporal time scales involved. For the phenomena already mentioned, we are interested in length scales ranging from Kolmogorov to Rossby.

**Physics of Surface Piercing Bodies**

8:52AM C02.00003 Physics of Surface Piercing Bodies

ANNE FULLERTON, Naval Surface Warfare Center — Most Navy vehicles operate at or near the free surface in order to meet mission requirements. As such, it is important to be able to accurately model and understand the physics of surface piercing bodies to inform the Navy of the vehicle’s performance during these operations. Continual advances in computing power and the ever-increasing availability of supercomputing resources have changed the way computational physics solvers are used in the Navy. However, even with modern High Performance Computing (HPC) resources, it is not currently feasible to directly simulate all of the relevant physics of Navy vehicles beneath, at, and above the free surface for necessary real-world time scales. Most modern computational physics codes address these shortcomings by resolving down to the smallest scales allowed by given computational resources and modeling phenomena that occur below the finest resolved scales. This work will discuss necessary physics of surface piercing bodies, current modeling techniques, and how they ultimately affect predictions which are used to inform the fleet.
High Reynolds Number Turbulent Flow will reduce skin friction drag at high Reynolds numbers (e.g., micro-fluidic devices). Yet, SHSs influence on fully developed turbulent boundary layers (TBL) is unclear. In order to develop SHSs that are related to the physics, material science, and manufacture of a wide variety of SHSs. Liquids undergoing laminar flow over SHSs may develop a Cassie-Baxter state at the flow boundary, and the presence of the gas pockets between rough surface asperities leads to a reduction in the shear stress compared to that of a smooth solid boundary, especially in flow channels where the slip length is on the order of the channel dimension (e.g., micro-fluidic devices). Yet, SHSs influence on fully developed turbulent boundary layers (TBL) is unclear. In order to develop SHSs that will reduce skin friction drag at high Reynolds numbers ($Re \geq 10^5$), our multi-university research group conducted a five-year effort focusing on five areas: (1) creation of optimized SHSs for high Reynolds number – we developed methodologies to manufacture specific SHSs with the desired surface energy and topology for the experimental examination of TBL modification at high Reynolds numbers; (2) examination of the interaction of near-wall flows with micro-scale surface gas pockets; (3) examination of the turbulence modification of micro-structured SHSs on five areas; (4) development of SHSs for passive and active gas replenishment to develop and maintain the Cassie-Baxter condition; and (5) experimental validation of SHS drag reduction at high Reynolds Numbers. This talk will present an overall summary of the efforts results and conclusions.

Sunday, November 24, 2019 8:00AM - 10:10AM – Session C03 Minisymposium: Fluid Dynamics in the Clinical Management of Intracranial Aneurysm 201 - Michael Levitt, University of Washington

8:00AM C03.00001 The use of fluid dynamics to predict success of intracranial aneurysm endovascular treatment: State of the Art and Potential for Translation to Clinical Use, M. LEVITT, M. BARBOUR, L. MARSH, V. CHIVUKULA, C. CHASSAGNE, C. KELLY, S. LEVY, Y. ZHENG, L. KIM, A. ALISEDA, University of Washington — Endovascular placement of coils or stents have become the preferred method for treatment of intracranial aneurysms. These minimally invasive procedures aim to create hemodynamics conditions that promote a stable thrombus that fills the entire aneurysm sac. No accurate exists, with failure to create a sac-filling thrombus occurring in 15-35% endovascular treatments that need retreatment involving significant risk to the patient and cost to the health care system. We simulate 60 patients treated with Flow Diverting Stents (FDS) or coils, both before and immediately after treatment. Synchrotron scans of the actual coils or stents deployed inside phantoms of the aneurysms are generated, allowing for comparison of the hemodynamics modeled with standard porous media versus homogenized anisotropic and heterogeneous models derived from the fully-resolved scans. We have developed both Eulerian and Lagrangian metrics to understand the hemodynamics that promote a successful embolization of the aneurysmal sac, and propose a risk score to predict the need to further treat or follow-up each patient during, or immediately after, endovascular treatment.

8:26AM C03.00002 Modeling of patient-specific blood flow in the brain: Are we there yet?, KRISTIAN VALEN-SENDSTAD, Simula Research Laboratory — A brain aneurysm is a focal weakening of the arterial wall, and rupture is associated with high rates of morbidity and mortality. Roughly

8:52AM C03.00003 Improving clinical decision-making with data: defining roles for computational fluid dynamics in aneurysm management, JASON M. DAVIES, Dept. of Neurosurgery & Dept. of Biomedical Informatics, University at Buffalo — Subjectivity plays an outsized role in the management of intracranial aneurysms (IA). Computational fluid dynamics may reduce variability and improve outcomes. In this study, we aimed to explore the utility of CFD in the management of UIAs in two domains, 1) identification of aneurysms that should be treated, and 2) prediction of occlusion outcomes for flow-diverted-treated aneurysms.

Methods: We identified aneurysm patients between September 2018 and June 2019 and computed the unruptured intracranial aneurysm treatment score (UIATS) as well as the Rupture Resemblance Score (RRS). We further identified patients treated with flow-diveters between 2011 and 2018. We computed 6 geometrical ($G$), 2 FD device-related ($D$), 4 pre-treatment (untreated, $U^*$) and 4 post-treatment (treated, $T^*$) hemodynamic features, which were then used in combination to train four neural network models.

Results: Treatment decisions were analyzed for 49 patients with 84 UIAs. Of the 42Conclusions: Hemodynamics contribute information relevant to the management of intracranial aneurysms. Incorporating data-driven management strategies should reduce variability in outcomes and improve patient care.

In collaboration with: Nikhil Paliwal, Dept. of Mechanical & Aerospace Eng. & Canon Stroke and Vascular Research Center, Univ. of Buffalo; Hui Meng, Dept. of Mechanical & Aerospace Engineering, Canon Stroke and Vascular Research Center, Dept. of Biomedical Engineering, Dept. of Neurosurgery, Univ. of Buffalo.

9:18AM C03.00004 Hemodynamics and Aneurysm Formation. MIN PARK, University of Virginia Health Center — Aneurysms develop due to a multitude of factors. Traditionally, research surrounding aneurysm formation has examined an individual's lifestyle and medical co-morbidities, such as hypertension, nicotine use, and a pre-existing family history. With improvements in technology and the ability to more accurately model hemodynamic forces, research has also focused on the role of hemodynamic forces on aneurysm development, remodeling, and the risk of aneurysm rupture. Computational fluid dynamic studies allow researchers to quantify the effects of fluid movement within a vessel and aneurysm. They can also identify parameters, such as wall shear stress and oscillatory shear index, which likely induce changes within the vessel to promote aneurysm formation and remodeling through complex biological pathways. We will review the current knowledge and beliefs regarding aneurysm formation and examine how computational fluid dynamics has added to our understanding of aneurysm pathophysiology and how it influences clinical decision making.

9:44AM C03.00005 Computational Fluid Dynamics and aneurysm wall mechanobiology: correlations between CFD, MRI vessel wall imaging and histology. MAHMOUD MOSSA-BASHA, University of Washington — TBD

Sunday, November 24, 2019 8:00AM - 10:10AM
Session C05 Sprays/Droplet Combustion and Ignition 204 - Jacqueline H. Chen, Sandia National Laboratories

8:00AM C05.00001 Flame structure analysis and flame stabilization in a turbulent swirling spray flame\(^1\), DANYAL MOHADDES, WENWEN XIE, MATTHIAS IHME, Stanford University — The quantitative prediction of the flow and combustion dynamics within highly turbulent environments encountered in modern aviation gas turbine engines remains an important challenge for the numerical combustion community. The use of large eddy simulation (LES) has become well-established for the analysis of such flows. Although a multitude of modelling approaches exist for combustion chemistry with known limitations in accuracy and computational cost, specific effects of a combustion model on a given simulation cannot be known a-priori. In this study, a turbulent swirling n-dodecane spray flame at ambient pressure is investigated using LES employing the Lagrangian point-particle approach and the eddy-viscosity model. The quantitative prediction of the flow and combustion dynamics within highly turbulent environments is studied. Experiments in the ZARM 4.7 s drop tower are conducted using a cryogenically-cooled test chamber that allows for pressures up to 60 bar. Initial experiments indicate that the hydrogen-oxygen diffusion flame is formed relatively close to the droplet surface. During the combustion process the surface of the LOX droplet appears to become covered by a water-ice layer, which ruptures to produce discrete, gaseous oxygen jets. External to the flame zone, the water vapor combustion product is observed to condense or freeze, forming a spherical shell around the burning droplet. The flame standoff distance and the droplet regression rate are investigated with shadowgraphy and OH chemiluminescence imaging. The experimental results are compared with the findings of numerical simulations conducted by the University of Washington.

8:13AM C05.00002 Liquid Oxygen Droplet Combustion in Hydrogen under Microgravity Conditions\(^1\), FLORIAN MEYER, CHRISTIAN EIGENBROD, ZARM Center of Applied Space Technology and Microgravity, VOLKER WAGNER, WOLFGANG PAA, IPHT Leibniz Institute of Photonic Technology, JAMES HALL, MICHAEL ZODY, JON FRYDMAN, JAMES HERMANSON, University of Washington — In liquid rocket propulsion the liquid oxygen (LOX) and liquid hydrogen system is widely used. Single oxygen droplets burning in gaseous hydrogen surrounds are investigated, representing the most basic element of this spray combustion process. The basic processes of droplet vaporization, mixture formation, ignition and combustion under cryogenic conditions in microgravity are studied. Experiments in the ZARM 4.7 s drop tower are conducted using a cryogenically-cooled test chamber that allows for pressures up to 60 bar. Initial experiments indicate that the hydrogen-oxygen diffusion flame is formed relatively close to the droplet surface. During the combustion process the surface of the LOX droplet appears to become covered by a water-ice layer, which ruptures to produce discrete, gaseous oxygen jets. External to the flame zone, the water vapor combustion product is observed to condense or freeze, forming a spherical shell around the burning droplet. The flame standoff distance and the droplet regression rate are investigated with shadowgraphy and OH chemiluminescence imaging. The experimental results are compared with the findings of numerical simulations conducted by the University of Washington.

8:26AM C05.00003 Numerical Simulation of Liquid Oxygen Droplet Combustion in Hydrogen\(^1\), JAMES HALL, MICHAEL ZODY, JON FRYDMAN, JAMES HERMANSON, University of Washington, FLORIAN MEYER, CHRISTIAN EIGENBROD, ZARM Center of Applied Space Technology and Microgravity, VOLKER WAGNER, WOLFGANG PAA, IPHT Leibniz Institute of Photonic Technology — In liquid rocket propulsion oxygen normally enters the combustion chamber as a dispersed phase, while the hydrogen fuel rapidly evaporates into a continuous, vapor phase. The ignition and combustion of a single, liquid oxygen droplet in gaseous hydrogen surroundings is thus the essential, first step in the subsequent spray combustion process. The OpenFOAM platform is used to calculate species concentrations, temperatures, heat release, and reactant consumption for this system. The simulations suggest that ignition, subsequent to the initial diffusion of gaseous oxygen into hydrogen, initially results in the appearance of two flame zones. As quasi-steady combustion is approached, these two flames merge. The resulting stable, quasi-steady flame, combined with the conductive heat transfer from the flame to the droplet surface is used to predict the oxygen droplet-combustion lifetime. These numerical simulations are conducted in parallel with drop-tower tests at ZARM. The calculated lifetime of a 1-mm liquid oxygen droplet undergoing combustion in gaseous hydrogen at 1 bar pressure and an initial temperature of 100 K is comparable to that observed in the drop-tower tests.

8:39AM C05.00004 ABSTRACT WITHDRAWN —

8:52AM C05.00005 Ignition Kernel Dynamics in a \(M = 3\) Flame holder. ESTEBAN CISNEROS-GARIBAY, University of Illinois at Urbana-Champaign, DAVID BUCHTA, The Center for Exascale Simulation of Plasma-Coupled Combustion, University of Illinois at Urbana-Champaign, JONATHAN FREUND, University of Illinois at Urbana-Champaign — The coupled mixing and reaction time scales of ignition in a supersonic flame-holding cavity flow are studied with detailed numerical simulations. A round jet ejects ethylene into the cavity under a \(M = 3, T = 440 \) K free-stream. The ignition (and subsequent sustained flame) are studied in detail, including direct comparisons with corresponding measurements. Two injection configurations are simulated: (i) vertical, from the cavity floor; and (ii) horizontal, from the cavity's 45° back wall. Ignition is seeded by a laser-induced breakdown (LIB), which creates radical species and locally heats the gas. Comparisons are made against measured excited hydroxyl radical (OH*) to assess prediction accuracy. The injection geometry significantly affects the direction in which ignition kernels (as quantified by OH mass fraction) advect and grow. Over the first 75 \(\mu s\), the turbulence mechanics that produce this and the observed large variance of ignition kernel statistics are studied and compared. These variances are greater than dependencies on the chemical kinetic parameters.
Temperature Compression Ignition Environments

9:05AM C05.00006 Direct Numerical Simulation of Multi-Injection Ignition in Low-Temperature Compression Ignition Environments
MARTIN RIETH, Sandia National Laboratories, MARC DAY, Lawrence Berkeley National Laboratory, SHUBHANGI BANSUDE, TIANFENG LIU, University of Connecticut, CHOL-BUM KWEO, JACOB TEMME, Army Research Laboratory, JACQUELINE CHEN, Sandia National Laboratories — Multi-injection strategies in combustion engines are known to be able to reduce pollutant emissions and improve ignition reliability. The latter is especially important in advanced compression ignition engine concepts relying on low-temperature high-efficiency operation or for engines operating at extreme high-altitude conditions. Under low-temperature conditions, fluid from the first injection does not ignite prior to mixing with fluid from the second injection, but provides pre-ignition chemical species and potentially a moderately elevated temperature. Fluid from the second injection mixes with this partially reacted mixture and its ignition is accelerated. However, the exact details of how pre-ignition species accelerate the ignition of the fluid from the second injection are not known. We will explore this with Direct Numerical Simulations (DNS) and, in particular, we will focus on understanding how particular chemical species and reaction pathways are responsible for accelerated ignition, identify the combustion modes and flame topologies present during ignition, and how these are affected by turbulent mixing and entrainment. To this end, we utilize a chemical explosive mode analysis, reaction-diffusion balances and related techniques.

9:18AM C05.00007 The impact of ignition on the occurrence and dynamics of multi-stage flames under shock tube conditions
TIANHAN ZHANG, YIGUANG JU, Princeton University — The laminar flame speeds and structures of ignition-assisted cool and warm n-heptane/air flames are studied computationally and analytically. The primary objective is to understand the effects of the ignition Damkohler number, mixture temperature, equivalence ratio, and pressure on the dynamics and structures of cool and warm flame propagation under shock tube conditions. Different transitions among cool, warm, and hot flames are examined. The results show that both cool and warm flame structures and propagation speeds change dramatically with the increase of the ignition Damkohler number and are affected by the initial temperature, equivalence ratio, pressure, and flame regimes. Furthermore, within the hot flame flammability limits, it shows that the cool flame speed has a non-monotonic dependence on the initial mixture temperature due to the negative temperature coefficient (NTC) effect, while the hot flame speed is divergently different and only increases monotonically with the initial temperature. Finally, compared with recent flame speed measurements using the shock tube, the simulation agrees well with the experimental data and demonstrates clearly how high speed and multi-stage flames affect the experimental observation and result in the NTC behavior.

9:31AM C05.00008 Three-dimensional effects in vorticity production, cellular instabilities, and transition to turbulence in focused-laser-induced ignition kernels
JONATHAN F. MACART, JONATHAN M. WANG, JONATHAN B. FREUND, University of Illinois at Urbana-Champaign — Ignition of combustible mixtures via laser-induced breakdown (LIB) involves interactions between thermal, chemical, and hydrodynamic processes. An initially axisymmetric plasma core has large density, pressure, and velocity gradients that lead to vorticity production, collapse of the plasma core, and a transition to three-dimensional evolution. These stages and their co-evolution with the thermochemical state are investigated in lean hydrogen-oxygen premixtures using three-dimensional detailed numerical simulations, in which the compressible Navier-Stokes and reactive species equations are solved assuming local thermodynamic equilibrium and charge neutrality. The initial LIB and gasdynamics are simulated in auxiliary calculations employing a two-temperature non-local thermodynamic equilibrium kinetic model and a radiative transfer equation. Three-dimensional vorticity is observed in the plasma core, but this initial vorticity diffuses during the collapse of the core and transition to laminar burning. After an initial period of laminar propagation, the flame develops a cellular instability, which accelerates the flame-front and produces flame-front vorticity leading to sustained turbulence.

9:44AM C05.00009 Hydrodynamic Ejection from a Laser-induced Breakdown and its Implications for Ignition
JONATHAN WANG, University of Illinois at Urbana-Champaign, DAVID BUCHTA, JONATHAN MACART, The Center for Exascale Simulation of Plasma-coupled Combustion, University of Illinois at Urbana-Champaign, JONATHAN FREUND, University of Illinois at Urbana-Champaign — Optical breakdown of a gas by a focused laser produces a high-temperature, high-pressure plasma kernel that expands rapidly and, in some cases, ejects hot gas along the laser axis. Traveling as a hot vortex ring, this ejected gas can reach distances several times the size of the plasma kernel and, in a combustible mixture, initiate flame growth away from the laser focal region. Under certain conditions (e.g. sub-atmospheric pressure), however, the ejection can fail to form or even reverse direction, altering the distribution of heat and radical species necessary for ignition. Detailed simulations of a model kernel, confirmed to reproducibly key experimental observations, show how the ejection and its reversal are caused by two primary mechanisms of vorticity production: tangential variations in the strength of the shock produced by the breakdown, and baroclinic generation in the trailing rarefaction. Relatively mild changes in the early-time kernel geometry alone—including, for example, a 20% increase in overall aspect ratio—can alter the subsequent interaction of auto-advecting vorticity and ultimately precipitate ejection failure or reversal. The ejection influences ignition via the competing effects of strain and heating.

9:57AM C05.00010 Thermal-Chemical Instability in Plasma-Assisted Combustion
HONGTAO ZHONG, MIKHAIL SHNEIDER, Department of Mechanical and Aerospace Engineering, Princeton University — In the flow of weakly ionized plasma, the transition from a diffusive volumetric discharge to a contracted localized filament is called plasma thermal instability. Traditionally, plasma thermal instability is controlled by the well-known thermal-ionization mechanism. However, endothermic/exothermic chemical reactions may bring new couplings between the reactive flow of weakly ionized plasma and chemical kinetics. In this work we developed a one-dimensional numerical model and studied the dynamics of thermal-chemical instability in a reactive mixture. Several key parameters including flow speed, gas pressure, initial temperature, and mixture composition are examined for their influence on triggering the thermal-chemical instability. This work will fill the knowledge gap in understanding the chemical kinetic effect on plasma instability in combustible mixtures and provide support for the future development of volumetric plasma ignition for ultra-lean combustion in advanced engines.

This work was supported by NSF and DOE Grant on plasma instability and plasma chemistry.
Details of its structure were unknown in part due to difficulties in experimental diagnostics. This work presents numerical simulations of the blue whirl, which reveals its flow structure and burning modes for the first time. The numerical model solves the unsteady, compressible, Navier-Stokes equations. The effects of combustion are modeled using a calibrated chemical-diffusive model. The domain is a cubical enclosure with sides which are 30 cm long. Circulation is imposed by forcing air through the corners and a constant flux of fuel is specified at the center of the bottom floor within a specified diameter. The upper boundary is an outflow condition and all other boundaries are non-slip. The results reveal a triple flame structure within the blue whirl and the influence of vortex breakdown on its burning and flow structure.

8:13AM C06.00002 Numerical description of blue whirls over liquid-fuel pools1. ANTONIO L SANCHEZ, University of California San Diego, JAIME CARPIO, Universidad Politecnica de Madrid, WILFRIED COENEN, University of California San Diego, ELAINE S. ORAN, Texas A&M University — Previous experiments of liquid-pool fires with ambient swirl have shown that, when the outer circulation is increased beyond a critical value, the existing fire whirl transitions to a new, fundamentally different configuration involving a lifted partially premixed front lying below a recirculating-flow bubble. The steady axisymmetric structure of this so-called blue whirl is investigated here by numerical methods. The problem is formulated with account taken of the boundary velocity induced by the thermal plume developing vertically above the axis, with a one-step Arrhenius description adopted for the heat release and a simple, optically thin approximation for H2O and CO2 radiation, the latter being fundamental for fuel vaporization. Integrations for increasing values of the swirl level are seen to describe all of the flow features observed in experiments, including the detachment and subsequent lifting of the flame edge, the emergence of vortex breakdown, and the establishment of a partially premixed front with a stoichiometric ring.

8:26AM C06.00003 Understanding Combustion in the Blue Whirl using Optical Diagnostics. SRIRAM BHARATH HARIHARAN, University of Maryland; Texas A&M University, YEJUN WANG, Texas A&M University, PAUL M. ANDERSON, US Army Research Laboratory, WARUNA D. KULATILAKA, Texas A&M University, MICHAEL J. GOLLNER, University of Maryland, ELAINE S. ORAN, Texas A&M University — The blue whirl is a soot-free flame that evolves from a traditional fire whirl in a regime close to the extinction limit for fire whirls. Previous work considered the physical and thermal structure of the flame and scaling approaches to predict transition to the blue whirl. To better understand the exact nature of combustion in the blue whirl, the present work uses chemiluminescence and planar laser-induced fluorescence (PLIF) techniques to visualize the reaction zone and distribution of radicals in the flame. Chemiluminescence images of excited-state OH* and CH* were obtained at 1 kHz and converted into a radial map using Abel inversion and the OH*/CH* intensity ratio was computed for the region around the bright blue vortex rim. A relationship between this ratio and the local equivalence ratio ($\Phi \in [0.7,1.3]$) was obtained by extrapolating from adiabatic methane-air flames stabilized over a Hencken calibration burner. In addition, PLIF images show that ground-state OH exists in high concentrations in the region of the bright blue ring and diminishes gradually into the post-flame region. Negligible presence of OH was observed in the blue conical region below the ring.

8:39AM C06.00004 On the Consistent Flamelet Model Formulation for Transcritical Fluid Flow and Combustion. ZHENG QIAO, YU LV, Department of Aerospace Engineering, Mississippi State University — Fluid flows in transcritical thermodynamics conditions have numerous applications in combustion engines and thermal energy devices. Under such conditions, the fluid behaviors are largely affected by the peculiar viscous transport properties and nonlinear thermodynamic relations. To achieve cost-effective modeling of transcritical fluids, the flamelet model has been exploited and investigated by a number of studies. This study focuses on the effects of model formulations on the flamelet predictions of transcritical fluids in both pure-mixing and combustion conditions. We first derive the consistent flamelet formulation based on Pitsch & Peters (1998) and then examine the constant Lewis assumption and the interspecies enthalpy flux on the flamelet predictions. For illustration purpose, the H2/air system at various thermal conditions is considered. Our study concluded that it is of importance to consider the detailed consistent model formulation in flamelet modeling of transcritical fluids.

8:52AM C06.00005 Modeling and Simulation of a H2/O2 Diffusion Flame under Cryogenic Condition using a Consistent Flamelet Formulation. YU LV, ZHENG QIAO, Department of Aerospace Engineering, Mississippi State University — Modeling of combustion phenomena under supercritical/transcritical conditions has recently gained growing interest due to the increasing applications of high-pressure combustion and energy devices. Under such thermodynamic conditions, combustion dynamics and flame characteristics are strongly affected by the peculiar thermo-diffusive transport properties and the nonlinear equilibrium-of-state relation. In this study, we first illustrate the effects through a flamelet study in which the comprehensive and consistent flamelet model is employed against the commonly used flamelet model formulation. Then the consistent flamelet model is employed to the LES of a GH2/LOx cryogenic flame based upon a newly developed computational framework. The simulation results will be extensively discussed and compared qualitatively with the experimental measurements by Candel et al. (2006).
8:13AM C07.00002 The 2019 MRV Challenge Experiment at Stanford University¹, CHRISTOPHER J. ELKINS, ANDREW J. BANKO, JOHN K. EATON, Stanford University, MICHAEL J. BENSON, United States Military Academy — Specific measurement techniques and Magnetic Resonance Velocimetry (MRV) results for the 2019 MRV Challenge experiment at Stanford University will be presented in detail. Some basic physics behind MRV as well as a general description of how pulse sequences (series of radio frequency pulses and applied magnetic field gradients) are used to make velocity measurements will be introduced. This will provide context for the motivation behind the challenge and the differences observed among the measurements by the participating labs since each lab uses a different pulse sequence in their own MRI system. Specific to the Stanford experiment, the equipment used and the overall setup of the square cross-section U-bend channel in the 3T magnet at the Richard M. Lucas Center for MRI at Stanford will be described. In addition, the parameters of the MRV pulse sequence and post processing steps of the data will be explained. Finally, an overview of the results and uncertainties will be given along with a discussion of the sources of these uncertainties.

¹Department of Defense

8:26AM C07.00003 2019 MRV Challenge: Hanyang University and Korea Basic Science Institute Results. , SIMON SONG, MUHAMMAD HAFIDZ ARIFFUDIN, DON-GWAN AN, CHAEHYUK IM, Hanyang University, SUKHOON OH, Korea Basic Science Institute — This presentation is part of the 2019 MRV Challenge, and represents the results of a combined team from Hanyang Univ. and KBSI. Four MRI research groups are supposed to make measurements in the same apparatus comprising a square cross section U-bend with a tight radius that will produce a highly three-dimensional flow field with turbulent flow separation. An inlet boundary layer trip marks the common coordinate origin of the flow in the channel. The apparatus being transferred between the research labs includes detailed flow conditioning to ensure that variations in supply and exit plumbing will not disrupt the test section flow. The test was conducted at a turbulent Reynolds number of 15,000 based on the hydraulic diameter. The presentation will focus on the methodology used including the MRI hardware and software, parameters for measurement, as well as the number of scans and overall scan duration, software sequence details, as well as post-processing and filtering techniques. In addition, details of the flow at several locations will be presented, along with estimates of uncertainty for each velocity component. Finally, an estimate of experimental effort — comprised of number of personnel involved and hours, costs, and other factors will be provided.

8:39AM C07.00004 Magnetic Resonance Velocimetry in High-Speed Turbulent Flows - Sources of Measurement Errors and a New Approach for Higher Accuracy , MARTIN BRUSCHEWSKI, KRISTINE JOHN, SVEN GRUNDMANN, University of Rostock — Magnetic Resonance Velocimetry (MRV) has great potential to become a versatile velocity measurement technique for applied fluid mechanics. One of the most dominant errors in MRV is the effect of displacement which describes the spatial misregistration of the acquired signal in a moving fluid. The overall aim of this study is to highlight the significance of displacement errors in conventional MRV and to provide an improved method. A new MRV sequence, named SYNC SPI (single point imaging with synchronized encoding) has been developed to significantly reduce this error. Measurements were performed in several test cases including a U-bend as part of the 2019 MRV Challenge. In comparison to conventional MRV, this sequence provides reliable velocity data for a wide range of flow velocities. It is shown that flow velocities up to 15 m/s can be accurately measured with this technique. The main disadvantage of the SYNC SPI sequence is the relatively long acquisition time. This disadvantage is partly resolved using a modern undersampling technique called Compressed Sensing to reduce the number of samples required to provide fully-resolved velocity data. It is shown that the acquisition time can be reduced by more than 70% while still maintaining high measurement accuracy.

8:52AM C07.00005 2019 MRV Challenge: Mayo Clinic Results¹, DANIEL BORUP, Mayo Clinic — This presentation is part of the 2019 MRV Challenge focus session. The results presented were obtained on a Philips 3T Elition X scanner. The flow geometry consisted of a U-bend with square cross section. The flow was fully turbulent with a bulk Reynolds number of 15,000. The flow loop was assembled and operated as described in the MRV Challenge instructions. This presentation will focus on details of the measurement including the choice of scan parameters, sequence design, and the overall measurement setup used to obtain data. The results from standard 3D Cartesian-trajectory imaging will be presented as a baseline, while data obtained in a shorter time using a “spiral readout” trajectory will be shown for comparison. Time-series data in 2D planes in the bend will also be presented to highlight any observations regarding the flow unsteadiness. The measurement uncertainties will also be presented.

¹Research Support from Philips Healthcare

9:05AM C07.00006 2019 MRV Challenge: Results and Comparisons, MICHAEL BENSON, U.S. Military Academy, CHRISTOPHER ELKINS, ANDREW BANKO, Stanford University, SIMON SONG, Hanyang University, SVEN GRUNDMANN, MARTIN BRUSCHEWSKI, University of Rostock, DANIEL BORUP, Mayo Clinic — This presentation is part of the 2019 Magnetic Resonance Velocimetry (MRV) Challenge and represents the combined results from all the participants of the challenge. Four research groups have made measurements in the same apparatus comprising a square cross section U-bend with a tight radius that will cause turbulent flow separation. An inlet boundary layer trip marks the common coordinate origin of the flow in the channel. The apparatus that was transferred between the research labs includes detailed flow conditioning to ensure that variations in supply and exit plumbing will not disrupt the test section flow. The test was conducted at a Reynolds Number of 15,000 based on the channel hydraulic diameter, and a tight radius U-Bend ensures a strongly three-dimensional flow field. This presentation will focus on the results from each team, which will be compared in the region near the boundary layer trip, at the entrance to and through the U-Bend, and through the exit passageway using velocity field contour plots, iso-surfaces, and quantities derived from the mean velocity components. Similarities and differences from the results will be presented which can provide insight into the opportunities that state of the art MRV provides to researchers.

9:18AM C07.00007 Investigation of Gas Turbine Cooling Flows Using Magnetic Resonance Velocimetry¹, WONTAE HWANG, SEUNGCHAN BAEK, SANGJOON LEE, JAEHYUN RYU, Seoul National University — Gas turbine blades are exposed to extreme high temperature, beyond the melting point of the material, thus various methods of advanced cooling are applied. Internal cooling extracts heat from the blade surface. Internal cooling within multiple channels inside the blade. These complex channels are spaced tightly together, and it is difficult to perform optical measurements of the flow. To overcome this problem, Magnetic Resonance Velocimetry (MRV) can be utilized to obtain the 3D flow field within these cooling channels. In this study, we demonstrate how we use MRV to analyze the complex flow field within turbine blade cooling structures such as a trailing edge internal channel which has rib turbulators and a thin sharp corner. The data can be used to provide quantitative validation for RANS and LES CFD.

¹This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korean government (MSIT) (No. 2017R1A2B4007372 and 2017R1A1A1015523)
Organizes the buffer layer structures near both upper and lower walls. Structures near the wall are more correlated with those near the opposite wall in DR flow, which implies that a large scale outer structure in the streamwise direction. Premultiplied two-dimensional spectra of streamwise velocity fluctuations show that the outer turbulence structure by adding polymer is modeled by the FENE-P model. It is found that in the DR flow, the length scale significantly increases, especially in the spacing between the volute wall and the blades is very small. Phase-locked experiments were conducted at the lower Reynolds number to ensure best measurement quality, yielding phase-locked velocity fields between the blades at five positions within a blade passing cycle. Alternating jet-wake structures are observed protruding from each blade passage around the impeller simultaneously. The varying size and shape of separation bubbles on the suction side of the blades is also analyzed as they rotate through an entire revolution.

9:44AM C07.00009 Mean Flow Field Measurements in Cavitating Flow Using Magnetic Resonance Velocimetry Supported by X-Ray and Particle Image Velocimetry

KRISTINE JOHN, MARTIN BRUSCHEWSKI, University of Rostock, SAAD JAHANGIR, WILLIAM HOGENDOORN, EVERT C. WAGNER, ROBERT F. MUDDE, CHRISTIAN POELMA, Technische Universiteit Delft, SVEN GRUNDMANN, University of Rostock — This presentation focusses on mean flow field measurements in cavitating flow using Magnetic Resonance Velocimetry (MRV). An intrinsic feature of MRV is its ability to measure without optical access. Optical refractions at the phase changes between liquid and vapor phases, which render optical data unusable, do not affect MRV. Moreover, the density of the nuclear spins that is used as a signal source for MRV is typically much higher inside the liquid phase. Voids based on signal intensity and measurements of the mean flow velocities in the liquid phase are possible. For a proof-of-concept, flow cavitation in a venturi is investigated. The MRV data is validated with PIV data up to the point of cavitation. For the cavitating cases, X-Ray measurements of the void mean fraction are used as support. It is shown that MRV can provide reliable velocity data. Quantitative void fraction measurements based on the signal intensity of MRV are cumbersome. Flow effects such as turbulence attenuate the signal intensity, which cannot be distinguished from signal voids caused by the vapor phase. The velocity data from MRV must be supported by void fraction data such as from X-Ray. Together, these two techniques provide a valuable tool for studies in cavitating flow.

9:57AM C07.00010 Purely Phase-Encoded Magnetic Resonance Mapping of Turbulence Anisotropy

BENEDICT NEWLING, AMY-RAE GAUTHIER, ALEXANDER ADAIR, Department of Physics, University of New Brunswick — The measurement of flow velocities much greater than 1 m/s can be a challenge for conventional magnetic resonance imaging (MRI) methods. Motion during the spatial encoding interval can lead to a variety of geometric and anemometric distortions. Purely phase-encoded MRI methods, such as SPRITE (single-point ramped imaging with T1 enhancement) can employ a short encoding interval (hundreds of microseconds) for the time-averaged measurement of fast flows. The interval is not only short, but also constant, which saves SPRITE from artefacts caused by interfaces in multi-phase flow. Most recently, we have been using SPRITE to measure mean-squared displacements in turbulent flow in order to quantify the anisotropy of velocity fluctuations. By analogy with diffusion tensor imaging, we measure the components of an eddy self-diffusivity tensor downstream of a Venturi constriction at Reynolds numbers on the order of 105.

8:00AM C08.00001 Modification of vortex shedding and turbulence statistics in a two-dimensional turbulent flow affected by polymers.

RURI HIDEMA, KENGO FUKUSHIMA, HIROSHI SUZUKI, Department of Chemical Science and Engineering, Kobe University. — FLUIDS AND PARTICLE ENGINEERING LABORATORY TEAM — An experimental study was performed to investigate the relationship between the extensional rheological properties of polymer solutions and vortex deformation in turbulent flow. In order to focus on the effect of extensional rheological properties of the fluids, polyethyleneoxide was added to two-dimensional (2D) turbulent flow. The 2D flow was self-standing flowing soap films that is relatively free from shear stresses. Therefore, the flow is advantageous as it examines the effect of the extensional rheological properties of polymers on the flow. In the study, the vortex shedding in 2D turbulent flow and turbulence statistics of the vortices in the flow were observed using interference patterns and particle image velocimetry (PIV). We found that the vortex shedding in the 2D flow was categorized into three types, and this was affected by the relaxation time of the polymer solutions. The modification of the vortices varied the energy transfer in 2D flows. We have also found that characteristic energy peak due to extensional rheology of the fluids.

8:13AM C08.00002 Organization of turbulence structures in polymer drag-reduced turbulent channel flow

KYOUNGYOUN KIM, Hanbat National University — To investigate turbulence structures in polymer drag-reduced (DR) channel flows, the spectra and correlations of the velocity fluctuations are examined by performing direct numerical simulations of viscoelastic turbulent channel flows of a drag reduction rate of 63%. The friction Reynolds number is Re = 395 and the stresses created by adding polymer is modeled by the FENE-P model. It is found that in the DR flow, the length scale significantly increases, especially in the streamwise direction. Premultiplied two-dimensional spectra of streamwise velocity fluctuations show that the outer turbulence structure in the DR flow differs from those in the Newtonian flow. Two-point correlations and conditional average flow fields reveal that the buffer layer structures near the wall are more correlated with those near the opposite wall in DR flow, which implies that a large scale outer structure organizes the buffer layer structures near both upper and lower walls.
8:26AM C08.00003 Turbulent Boundary-Layer of Power-law Fluids Near a Position of Separation. JULIANA LOUREIRO, ATILA SILVA FREIRE, Federal University of Rio de Janeiro — The study describes the turbulent boundary layer structure near and at a separation point for power-law fluid flows. Experimental work is performed for flow of water and a 0.1% carboxymethyl cellulose (CMC) water blend, over an asymmetric plane diffuser with 30-degree slope. The flow index $n$ and the consistency parameter $K$ are respectively 0.86 and 0.00753 (Pa s$^n$). Particle Image Velocimetry and Laser Doppler Velocimetry are used to introduce profiles of local mean velocity, turbulent shear stresses at the points of separation, reattachment and in the recirculation region. The location of the separation and reattachment points are described in terms of changes in the generalized Reynolds number based on the channel height and the shear stress conducted for finite Reynolds numbers. The work reports large changes in the length of the separation regions and discusses the local solutions of Goldstein (1948) and Stratford (1959). In the fully viscous region, the mean velocity is shown to vary as $y^{(n+1)/n}$, as expected from the local analytical solution, with $y$ as the distance from the wall. In the fully turbulent region, the mean velocity profile follows a $y^{1/2}$ law, being thus independent of rheology of the fluid.

8:39AM C08.00004 ABSTRACT WITHDRAWN —

8:52AM C08.00005 Exact coherent structures in two-dimensional viscoelastic channel flow. JACOB PAGE, University of Cambridge, YVES DUBIEF, University of Vermont, RICH KERSWELL, University of Cambridge — Elasto-inertial turbulence (EIT) is a recently discovered flow state in dilute polymer solutions that is strikingly different to quasi-Newtonian, drag-reduced flows. EIT is largely two-dimensional; its dominant flow features are thin sheet-like structures of polymer stress with attached patches of intense spanwise vorticity. In this talk we explore the mechanics underpinning EIT by searching for exact coherent structures in elasto-inertial planar channel flows. The structures we find are all connected to a recently discovered linear instability (Garg et al, Phys. Rev. Lett. 121, 2018) of the basic state that exists at moderate elasticities $Wi < Re < \mu^3$. Just beyond the point of marginal stability ($Wi \approx 25$, $Re \sim 50$) the universal attractor is a relative periodic orbit (RPO) featuring a pair of large amplitude sheets that meet at the centreline. This RPO bifurcates off a strongly subcritical travelling wave that exists for Weissenberg numbers as low as $Wi \sim 10$. We perform branch continuation of this travelling wave upwards in Reynolds number to explore its overlap with EIT. Time permitting, we will also discuss the physical mechanisms at play in the new linear instability.

9:05AM C08.00006 Critical layers, Tollmien-Schlichting waves and elasto-inertial turbulence. ASHWIN SHEKAR, University of Wisconsin-Madison, RYAN MCMULLEN, BEVERLEY MCKEON, Caltech, MICHAEL GRAHAM, University of Wisconsin-Madison — We describe direct numerical simulations (DNS) and linearized analyses of channel flow turbulence in a FENE-P fluid in the elasto-inertial turbulence (EIT) regime. Simulations at low (transitional) Reynolds numbers are shown to display localized polynomial stretch fluctuations very similar to structures arising from linear stability (Tollmien-Schlichting (TS) modes) and resolvent analyses: i.e., critical-layer structures localized where the mean fluid velocity equals the wavespeed. Self-sustained nonlinear TS waves display stagnation points that generate sheets of large polymer stretch. These kinematics may be the genesis of similar structures in EIT. We also describe a new self-sustaining elastoinertial state which we term the lower branch attractor (LBA), which has very small amplitude and whose structure closely resembles that of the linear TS mode. A tentative bifurcation scenario describing our observations is described. We also identify the minimal flow unit for EIT, which at low Reynolds number continues to exhibit localized stress fluctuations. Finally, resolvent analysis and transient simulations of the linearized problem shed light on the origins of the mechanisms leading to amplification of fluctuations and thus to the bypass-transition nature of the onset of EIT.

8:18AM C08.00007 What do we mean by the mean conformation tensor (in viscoelastic turbulence)? ISMAIL HAMEDUDDIN, Norton-Rose-Fullbright, TAMER ZAKI, Johns Hopkins University — The popular arithmetic mean conformation tensor frequently used in the analysis of turbulent viscoelastic flows is not a good representative of the ensemble. Alternative means more faithful to the tensorial character of the conformation tensor are evaluated, namely, the geometric and square root of the Reynolds number. It is noteworthy that this primary instability is non-hysteretic and appears in the absence of perturbations of the elastic, viscous, and inertial forces on the ejected droplet size. These simulations serve as a departure point for further work involving three-dimensional simulations of atomisation processes of viscoelastic jets.

9:31AM C08.00008 En Route to the Maximum Drag Reduction Asymptote. GEORGE CHOUEIR, JOSE LOPEZ, ATUL VARSHNEY, BJORN HOF, IST Austria — We report the results of an experimental investigation into the stability and transition of a supersonic pipe flow. Wave stability is investigated at different Reynolds number $O(1)$, provided that the shear stress (and hence the Weissenberg number) is sufficiently large, all the way to the maximum drag reduction (MDR) asymptote for dilute polymer solutions. At onset the amplitude of streamwise velocity fluctuations is found to grow with the square of the Reynolds number. It is noteworthy that this primary instability is non-hysteretic and appears in the absence of perturbations and curved streamlines. The flow structures observed closely resemble those of the unstable mode discovered in a recent stability analysis. Further from onset, a secondary instability is found where the azimuthal symmetry is broken and inclined streaks of high amplitude appear in the near wall region. These streak patterns resemble the typical flow structures found in MDR turbulence at higher Reynolds numbers.

9:44AM C08.00009 Two-dimensional direct numerical simulations of viscoelastic jets. KONSTANTINOS ZINELIS, THOMAS ABDIE, RICARDO CONSTATE-AMORES, OMAR MATAR, Imperial College London — The numerical simulation of spray formation in a non-Newtonian fluid offers substantial challenges and is central to numerous industrial applications such as spray-drying. The aim of the present work is to set the basis for the numerical examination of non-Newtonian atomisation and spray systems. To achieve this, a Direct Numerical Simulations (DNS) approach is followed where all the temporal and spatial scales are resolved completely. We begin with the simulation of two-dimensional numerical simulations of an Oldroyd-B impulse jet as well as a jet with a constant release velocity into a stagnant gaseous phase using the volume-of-fluid technique to capture the interface and the S-configuration transformation for the solution of the viscoelastic constitutive equation. This permits the exploration of parameter space, capturing the effect of the elastic, viscous, and inertial forces on the ejected droplet size. These simulations serve as a departure point for further work involving three-dimensional simulations of atomisation processes of viscoelastic jets.

1Engineering and Physical Sciences Research Council, UK, i-case studentship (sponsored by Johnson Matthey) for Konstantinos Zinelis
9:57AM C08.00010 A Well-Conditioned Numerical Method for Resolvent Analysis of Viscoelastic Channel Flows1, GOKUL HARIHARAN, Department of Chemical Engineering and Materials Science, University of Minnesota, MIHAILO JOVANOVIC, Ming Hsieh Department of Electrical and Computer Engineering, University of Southern California, SATISH KUMAR, Department of Chemical Engineering and Materials Science, University of Minnesota — Linear analyses provide useful information about the potential for transition to nonlinear states. While a modal approach furnishes information about long-time growth or decay of initial conditions, non-modal approaches give insight into the amplification of disturbances in a linearly stable flow. Here, we conduct non-modal analysis of inertialless 2D viscoelastic channel flows. Our analysis reveals large stress gradients in the near-wall region (for plane Poiseuille flow) and in the channel center (for plane Couette flow). These steep stress gradients can only be resolved using recently developed well-conditioned spectral methods, e.g., the ultraspherical and spectral integration methods. Furthermore, even if the discretization method is well-conditioned, computation of frequency-responses can be erroneous if singular values are obtained as the eigenvalues of a cascade connection of the resolvent operator with its adjoint. We address this issue by introducing a feedback interconnected system that avoids matrix inverses and allows reliable frequency-response calculations of viscoelastic channel flows at high Weissenberg numbers (~500). The steep stress gradients that we identify may play a role in explaining recent experiments concerning transition to elastic turbulence.

1National Science Foundation

Sunday, November 24, 2019 8:00AM - 10:10AM — Session C09 Turbines: General 213 - Brent Houchens, Sandia National Laboratories

8:00AM C09.00001 Influence of Near-blade Hydrodynamics on Cross-flow Turbine Performance, ABIGALE SNOTLAND, BRIAN POLAGYE, OWEN WILLIAMS, University of Washington — Cross-Flow turbines are a promising technology for harvesting kinetic energy from wind and water currents. The hydrodynamics are complex and rapid changes in angle of attack lead to phenomena such as dynamic stall and periodic vortex shedding. A robust understanding of local flow features at the turbine blades and their impact on phase-averaged performance is essential for turbine design and can inform control strategy development. Phase-averaged 2D planar PIV data is examined for both optimal (maximum power generation) and sub-optimal rotation rates over the entire sweep of a two-bladed, cross-flow turbine. The phase and rotation-rate dependent, near-blade/wake hydrodynamics are examined in concert with phase-averaged performance data. The duration/severity of flow reversal on, and detachment from, the blades appear critical to average performance. Strong stall and vortex interactions occur over most of the turbine rotation for the sub-optimal case, possibly producing parasitic forces that outweigh any increases in lift from the leading-edge vortex. At the optimal rotation rate, vortex shedding on the upstream blade is significantly delayed, and the downstream blade is weakly stalled. This likely explains the difference in power output between the two cases.

8:13AM C09.00002 Improving the accuracy of wind farm LES using filtered actuator disk theory corrections1, CARL SHAPIRO, DENNICE GAYME, CHARLES MENEVEAU, Johns Hopkins University — The utility of large eddy simulations (LES) of large wind farms that employ the actuator disk model (ADM) are limited by over-prediction of power that can exceed 10% at typical resolutions. Computational restrictions require spatial filtering of the actuator disk thrust force, which is distributed equally across the swept area of the rotor blades, resulting in an under-prediction of the shed vorticity. The filtered ADM, which models the wind turbine wake as concentric semi-infinite vortex cylinders, provides a basis for analytically correcting this error in simulation. When compared to simulations with various filter widths and grid sizes, the filtered ADM accurately predicts the power coefficient measured in simulations. An analytic correction factor is then derived from the filtered ADM that collapses the power coefficient measured in simulations onto the theoretical axial momentum theory predictions. This approach eliminates the need for highly refined numerical grids or empirical correction factors.

8:26AM C09.00003 LES of microscale winds in complex configurations1, LAURENT BRICTEUX, STEPHANIE ZEOLI, MONCEF GAZDALLAH, University of Mons, PAULINA PANKO-OPRYCH, West Pomeranian University of Technology, Szczecin, GREGOIRE LEROY, 3E, PIERRE BENARD, INSa Rouen Normandie / CORIA — This contribution concerns wall modeled large eddy simulations (WMLES) of turbulent winds in complex geometries that are relevant for wind energy problems: either in the built environment (e.g. generic buildings) or complex terrains (e.g. Askervein Hill). This work is performed in the framework of developing simplified operational models to be used for wind turbine siting. It is proposed to investigate the influence of the wall modeling strategy and the turbulent inflow boundary condition on the flow diagnostics relevant for wind turbine siting (local velocity and turbulence profiles). The validity and quality of an original turbulence inflow generation method are also assessed. This boundary condition is based on the algorithm of Mann and generates realistic atmospheric turbulence with a prescribed spectrum and lengthscale.

8:39AM C09.00004 Power measurements in a scale model wind farm: Results from varying array size, arrangement, spacing, and setpoints, DAN HOUCK, EDWIN COWEN, Cornell University — The current trend in wind energy research is to optimize wind farms as opposed to optimizing individual turbines. There is also an emerging idea to consider the wind turbines themselves as actuators that can be used to intentionally and beneficially manipulate the flow to improve the power output of the wind farm. To this end, we completed a series of experiments with an array of 18 model-scale wind turbines in a 2 m wide flume testing changes in the number, arrangement, and spacing of the turbines as well as the setpoint, or power production, of each turbine. Each treatment case is compared to a similar control case that was arranged and operated more conventionally with all turbines attempting maximum power production. A highly accurate torque transducer provides calibrations allowing non-intrusive mechanical power measurements of each turbine. Comparisons are made on the basis of overall power output, array efficiency (total power output of the N-turbine array divided by N of an upstream turbine operating at max power), and power density (power per area). Particle image velocimetry (PIV) further reveals the fluid dynamics at work to create any improvements in power.
A novel wind energy harvester with no external moving parts is demonstrated at one-third scale (0.5-meter chord) in wind tunnel tests. The device uses mirrored airfoil-pairs to create suction. This pulls air out from ducts internal to the foils, through air-jet orifices on the low-pressure sides of the foils, and into the external incident wind. Power is transmitted pneumatically through the center of the foils to an internal turbine-generator. In the high-performance operating mode at high angle-of-attack, a mechanical power transmission of nearly one-half of the Betz limit is achieved. However, this high angle-of-attack configuration is susceptible to aero-acoustic instabilities which can diminish the performance to as low as one-sixth of the Betz limit. These instabilities are investigated here for a configuration with all air-jets covered. Pressure measurements are made on the low-pressure sides of the foils and the break in symmetry associated with the instability is documented. Particle image velocimetry is used to characterize the flow field before and after onset of the instability. SNL is managed and operated by NTI under DOE NNSA contract DE-NA0003525.

9:05AM C09.00006 Experimental comparison of HAWTs with hydrostatic and regular transmissions, HELBER ANTONIO ESQUIVEL-PUENTES, ANDREA VACCA, School of Mechanical Engineering, Purdue University, LEONARDO P. CHAMORRO, Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign, JOSE GARCIA-BRAVO, School of Engineering Technology, Purdue University, HUMBERTO BOCANEGRA-EVANS, DAVID WARSINGER, WALTER GUTIERREZ, LUCIANO CASTILLO, School of Mechanical Engineering, Purdue University — The performance of a horizontal axis wind turbine (HAWT) with hydrostatic transmission was compared with that of a standard unit using well-controlled experiments. The power output of the hydrostatic unit is used for electricity generation, and/or reverse osmosis to obtain fresh water. Furthermore, the hydrostatic transmission allows for moving the major electro-mechanical components located in the hub to the ground level. The associated changes resulted in reductions of approximately 30% of the total mass of the unit, and of about 7 to 14% of the cost of the energy. The reconfiguration of the structure of the turbine also implied changes in the response of the system to turbulence. We assessed such effects across scales considering changes in the transfer function of the spectrum of the power output, following Tobin et al. (2015).

9:18AM C09.00007 Reliability of Long-term Lidar-based Wind Measurements for Various Wind Energy Applications, JAY PRAKASH GOIT, Department of Mechanical Engineering, Kindai University, Japan, SUSUMU SHIMADA, TETSUYA KOGAKI, National Institute of Advanced Industrial Science and Technology, Japan — In this work, we conduct a long-term measurement campaign (approximately one year) using a profiling Lidar, in order to investigate whether Lidars can be used as a reliable alternative to meteorological masts for wind energy applications. It is found that the Lidar-measured wind speed showed good agreement with those measured using sonic anemometers mounted to the neighboring meteorological mast, with the coefficient of determination ($R^2 > 0.99$). However, comparison of the standard deviations shows larger degree of variations, with $R^2$ between 0.92 and 0.97. Turbulence intensities computed for the 90th percentile of the standard deviation show that the Lidar-measured turbulence intensities are larger by roughly 2% than those measured by the sonic anemeter. But the gust factors for peak wind speeds converge roughly to 1.9 during strong wind speed for both the devices. Finally, wind speed and turbulence distribution for the Lidar and sonic anemometer are used to compute fatigue load for NREL 5-MW reference wind turbine using aerelastic simulation. The 20 years lifetime DELs for the Lidar wind speed are higher than those for the sonic anemometer wind speeds, by 6% for the blade root bending moment and by 13% for the tower based bending moment.

9:31AM C09.00008 Actuator-line simulations of wind turbines with block-structured adaptive mesh refinement, MAHESH NATARAJAN, HARISWARAN SITARAMAN, SHREYAS ANANTHAN, MICHAEL ALAN SPRAGUE, National Renewable Energy Laboratory — Wind turbine parametrization methods such as the actuator disk (ADM) or actuator line methods (ALM) have shown good promise in determining power generation and loads on the turbine blades. However, performing such simulations in a cost-effective manner is a challenging task, due to the wide range of scales involved. The scales in the atmospheric boundary layer (ABL) range from 1 km to scales in the wake region that are 1 m. Adaptive mesh refinement techniques are well suited for this scenario, and will enable well-resolved simulations that can capture turbulent structures across multiple length scales. In this work, we implement an ALM model in two frameworks - a compressible and an incompressible flow solver - both developed within the block-structured adaptive mesh refinement (AMR) framework of AMReX [1], and compare their performance. Computational scaling studies are done on a single turbine configuration, and compared with Nalu-Wind [2] - an unstructured CFD solver for wind turbine simulations.

9:44AM C09.00009 Biomimetic individual pitch control for wind turbines, MARION COQUELET, UCLouvain - UMONS, LAURENT BRICTEUX, Universite de Mons (UMONS), MAXIME LEJEUNE, PHILIPPE CHATELAIN, Universite catholique de Louvain (UCLouvain) — Individual Pitch Control (IPC) has proved efficient in reducing fatigue loads on wind turbines. As 1P (once-per-revolution) blade loads are significant due to wind shear or tower shadow effect, their alleviation implies a rhythmic behavior in the changes of the blade pitch angles. This work relies on Large Eddy Simulations (LES) to demonstrate the effectiveness of a biomimetic architecture for IPC. The high-fidelity simulation of the flow physics is essential to assess the performances of the controller. It is performed by an in-house lifting-lines-enabled Vortex Particle-Mesh method, dealing with synthetic turbulence and wind shear at the inflow. The individual pitch controller is based on Central Pattern Generators (CPGs). CPGs produce, from very simple inputs, rhythmic outputs that drive repetitive motions like walking or breathing. The specificity of these networks is their ability to operate autonomously. They are here implemented as coupled non-linear oscillators, capable of producing coordinated rhythmic patterns and driven by a knowledge of the upstream flow conditions. The latter are reconstructed online by an Extended Kalman Filter processing the loads experienced by the individual blades.

1Funding from the European Research Council under the European Unions Horizon 2020 research program. Computational resources made available on the Tier-1 supercomputer funded by the Walloon Region.
The mean velocity is plotted in defect formulation, i.e., $U - U(\eta_m)/\eta_m$. The intermediate-scaled mean velocity and variance exhibit Reynolds-number invariance over a certain region around $\eta = 1$. This implies existence of a Reynolds-number independent log law in terms of the intermediate variables for the mean velocity and variance. The classical “Karman constant” and “Townsend-Perry constant” are expressed in terms of the log-law constants obtained from the intermediate scaling and their dependence on Reynolds number examined. The present work suggests a three-layer asymptotic structure for the TBL, with each layer governed by distinct length and velocity scales, which results in two overlap layers (Afzal. Ing.-Arch. 1982). We discuss the relevance of the power/log law behavior of the mean velocity in the overlap layers, based on the ratio of the velocity scales of the adjacent layers.

We acknowledge financial support from EPSRC (EP/1037938/1).

**8:13AM C10.00002 Log-law & power-law: local self-similarity of a flat-plate boundary layer**

JOSEPH RUAN, GUILLAUME BLANQUART, California Institute of Technology — A large controversy in the previous decade for flat-plate boundary layers was on the scaling of the defect layer with respect to different velocity scales, made prominent by George & Castillo (1997). The lack of enough large Reynolds number experiments and simulations makes the choice of appropriate velocity scale rather difficult. We show mathematically that the differences between the scaling descriptions (using the free-stream velocity or the friction velocity as a scaling parameter) may in fact be negligible for local regions of the boundary layer. We verify from a variety of simulation frameworks that the results from filtered-lifting-line-theory and LES using the actuator line model are in excellent agreement, as expected, and agree well with the measurements. The results suggest that when computing the forces along the blade, filtered-lifting-line-theory, LES using the actuator line model, and blade resolved DES agree well with the experiment and the differences between each method are small. However, when comparing the flow fields downstream, blade resolved simulations are able to accurately capture the tip-vortex, whereas the actuator line model cannot always capture the flow details from the tip vortex.

**8:26AM C10.00003 A Spectral-Scaling Based Extension to the Attached Eddy Model of Wall-Turbulence**

DILEEP CHANDRAN, JASON MONTY, IVAN MARUSIC, The University of Melbourne — An extension to the attached eddy model (AEM) for the logarithmic region of turbulent boundary layers is presented here. The extension is driven by the scaling of two-dimensional (2-D) spectra of the streamwise velocity component, measured at friction Reynolds numbers ranging from 2400 to 26000. The conventional AEM assumes the boundary layer to be populated with hierarchies of self-similar wall-attached (TypeA) eddies alone. While TypeA eddies represent the dominant energetic large-scale motions at high Reynolds numbers, the scales that are not represented by such eddies are observed to carry a significant proportion of the total kinetic energy. Therefore, in the present study, we propose an extended AEM that incorporates two additional representative eddies. These eddies, named TypeCA and TypeSS, represent the self-similar but wall-detached low-Reynolds number features, and the non-self-similar wall-attached structures, respectively. The extended AEM is observed to predict reasonably well a greater range of energetic length scales and capture the low- and high-Reynolds number scaling trends in the 2-D spectra of all three velocity components.

**8:39AM C10.00004 Spatio-Temporal Characteristics of Coherent Structures in Shear-Dominated Flows**

TAYGUN RECEP GUNGOR, AYSE GUL GUNGOR, Istanbul Technical University, YVAN MA-CIEL, Universit Laval, MARK PHIL SIMENS, Universidad Politecnica de Madrid — The energy and Reynolds stress carrying structures are investigated using three different numerical simulation databases. The first and second databases are non-equilibrium adverse gradient pressure (APG) turbulent boundary layers (TBLs) with $Re_{\theta}$ reaching 8000. In the second case, the turbulent activity in the inner layer ($y/\delta < 0.1$) is artificially eliminated to examine outer of layer APG TBLs in the absence of near-wall turbulent activity. The last one is a homogeneous shear flow (HSF) database that provides information about a shear dominated flow without a wall. The turbulence statistics and structures in three flow cases are compared to understand similarities and differences between the outer layer of APG TBLs and HSF. Results of the manipulated APG TBL indicate that outer layer turbulence sustains itself when there is no turbulence activity in the inner layer and the spatial-temporal characteristics of the energetic structures are similar to the structures found in the original APG TBL. Furthermore, Reynolds stress carrying structures in the APG TBLs resemble the ones in HSF when their dimensions are scaled with the Corrsin length scale.

Reynolds number dependence of turbulence statistics near the turbulent/non-turbulent interfacial layer in turbulent boundary layer. XINXIAN ZHANG, TO-MOAKI WATANABE, KOJI NAGATA, Nagoya University — Direct numerical simulations (DNS) of a temporally developing turbulent boundary layer (TBL) are performed for investigating the Reynolds dependence of the turbulent/non-turbulent interfacial layer (TNTI layer). The Reynolds number based on the momentum thickness ranges from 2000 to 13000 in the present DNS. The outer edge of the TNTI layer, called the irrotational boundary, is detected as an isosurface of vorticity magnitude, and the conditional statistics are calculated conditioned on the distance from the irrotational boundary. The results show that the mean thickness of the TNTI layer divided by the Kolmogorov scale is almost constant for different Reynolds numbers when the Kolmogorov scale is taken near the TNTI layer. On the other hand, the mean thickness normalized by Taylor microscale decreases as the Reynolds number increases. Influence of the wall on the statistics near the TNTI layer are shown to be stronger for a lower Reynolds number. Geometry of the irrotational boundary is also studied for the mean curvature and surface area. It is shown that the mean curvature normalized by the Kolmogorov scale has a similar probability density function for all the Reynolds numbers while the surface area increases with the Reynolds number.

Where is the wall? RICARDO GARCIA-MAYORAL, JOSEPH IBRAHIM, GARAZI GOMEZ-DE-SEGURA, University of Cambridge — Textured surfaces with small texture size can increase or reduce turbulent drag, compared to a smooth wall, by imposing different virtual origins for the different streamwise and spanwise components. We extend this idea by imposing different virtual origins for all three velocities using Robin, slip-length-like boundary conditions in direct numerical simulations. We show that the change in drag depends only on the offset between the virtual origin for the mean velocity profile, typically set by the streamwise slip length, and the virtual origin for turbulence (embodied by the quasi-streamwise vortices of the near-wall core), set by the wall-normal and spanwise slip lengths. We demonstrate that, other than by the offset between these origins, turbulence remains essentially smooth-wall-like, and show how to obtain the position of the virtual origins for the mean velocity and for turbulence from the three slip-length coefficients, and from them the change in drag.

Quantifying Reynolds stresses in the planar transitional T3-serious flows. FAN TANG, WEI-TAO BI, ZHEN-SU SHE, State Key Lab for Turb. & Complex Sys., College of Engg., Peking Univ. — The transitional flow with a rapid change of friction coefficient in the streamwise direction is a subject of enormous technological impact, but difficult to quantify, even for simple geometry such as flow passing a smooth flat plate. Recently, a comprehensive theory of turbulent boundary layer is constructed via a Lie-group symmetry approach, yielding a multi-layer description of four stress lengths in the wall-normal direction. Here, we report its extension to transitional TBL, with a unified quantitative description for both the Reynolds shear stress and normal stresses (turbulence intensities) throughout the transition region. Specifically, the transition and subsequent evolution to fully developed TBL are quantified with a streamwise multi-layer description (starting from the leading edge) of two key parameters (a near-wall eddy length, and kappa — a bulk flow parameter), which display a scaling change from laminar to turbulent regime. For the T3-serious planar transitional flows with varying incoming turbulence intensity and pressure gradient covering both natural and bypass transitions, the new theory predicts simultaneously, for the first time, the friction coefficient and wall-normal mean (velocity and turbulent kinetic energy) profiles throughout the entire flow domain. In summary, all four Reynolds stress components are successfully predicted for transitional planar boundary layer, promising future simular and more accurate alternative model for engineering applications.

Near-asymptotics overlap solutions for transport moments in turbulent channels and boundary layers. WILLIAM GEORGE, Dept. of Aeronautics, Imperial College of London, London, UK, JEAN-MARC FOUCAUT, JEAN-PHILIPPE LAVAL, Univ. Lille, Onera, CNRS, Centrale Lille, Arts et Mtiens Paris Tech, FRE 2017 - LMFL - Laboratoire de Mecanique des Fluides de Lille Kamp de Friet, — The log profile overlap solutions for turbulent channel have been complemented recently by solutions for the dissipation\(^1\), \(\varepsilon\) and the kinetic energy\(^2\), \(\langle q^2\rangle/2\). The dissipation varies as \(1/y^\alpha\), while the turbulence kinetic energy varies logarithmically. The Reynolds shear stress is nearly constant. We show from similar arguments that the transport moments, \(\langle \theta T \rangle / \langle q^2 \rangle/2 \) also vary logarithmically. So all the terms in the kinetic energy balance in overlap region, \(\langle \theta T \rangle / \langle q^2 \rangle/2 = \varepsilon \), vary inversely with \(y^\alpha\). Boundary layer results are the power-law equivalents, but indistinguishable. Both are shown to be consistent with recent experimental and DNS data. This presents a problem for the usual eddy viscosity models for this region, \(\nu_t \propto \langle q^2 \rangle/2 \varepsilon\), since both cannot be true. Revealing Some Roots to Our Uncertainty Regarding Values of Von Kármán Constants. HASSAN NAGIB, IIT, Chicago, USA, LUCIA MASCOTELLI, GABRIELE BELLANI, ALESSANDRO TALAMELI, Università di Bologna, Forlì, Italy — Three different fits of logarithmic dependence of centerline velocity, \(U^{+}_{CL}\), in pipe flow at CICLOPE, with nearly equal representation of experimental data over range 8,000 < \(Re_{\nu}\) < 40,000 have been used to generate synthetic data that are densely spaced with Reynolds number. A higher order term proportional to inverse of \(Re_{\nu}\) was incorporated into one. Two approaches to uncertainty analysis of three sets of synthetic data were used to study dependence of uncertainty of extracted values of \(k_{CL}\): Random Sampling of Full Range of Uncertainty and All Possible Perturbations of Extreme Uncertainties. Role of low Reynolds number data and accuracy of pressure transducer used to measure pressure gradient along pipe were examined. Results reveal following mean values and uncertainties from measurements by the multiple-transducer pressure scanner that was used: \(k_{CL} = 0.44 \pm 0.006\) for all Reynolds numbers, and \(\kappa_{CL} = 0.45 \pm 0.038\) for data with \(Re_{\nu} > 12,000\). More significantly, we conclude that CICLOPE requires a more accurate pressure scanning method for determining \(dp/dz\) e.g., using a Scanivalve connected to a single more accurate pressure transducer. Such an approach has potential of reducing uncertainty by an order of magnitude.

Turbulent flow field in the viscous sublayer: statistics and structures. SANTOKHUM SANKAR, Dept. of Mechanical Eng & Saint Anthony Falls Lab, Univ of Minnesota, JIARONG HONG, Department of Mechanical Engineering & Saint Anthony Falls Lab, University of Minnesota — The study of wall-bounded turbulence has focused on the logarithmic region above the wall. However, the need to unravel the effects of sublayer roughness, turbulence remains essentially smooth-wall-like, and show how to obtain the position of the virtual origins for the mean velocity and for turbulence from the three slip-length coefficients, and from them the change in drag.

8:13AM C11.00002 Self-similar invariant solution in the near-wall region of a turbulent boundary layer at very high Reynolds numbers1, TOBIAS M. SCHNEIDER, SAAJAD AZIMI, EPFL - Swiss Federal Institute of Technology Lausanne — At sufficiently high Reynolds numbers, shear-flow turbulence close to a wall acquires universal properties. When length and velocity are rescaled by appropriate characteristic scales of the turbulent flow and thereby measured in inner units, the statistical properties of the flow become independent of the Reynolds number. We demonstrate the existence of a wall-attached exact invariant solution of the fully nonlinear 3D Navier-Stokes equations for a parallel boundary layer that captures the characteristic self-similar scaling of near-wall turbulent structures. The solution branch can be followed up to Re = 500,000 corresponding to a friction Reynolds number in the millions. Combined theoretical and numerical evidence suggests that the solution is asymptotically self-similar and exactly scales in inner units for Reynolds numbers tending to infinity. Demonstrating the existence of invariant solutions that captures the self-similar scaling properties of turbulence in the near-wall region is a step towards extending the dynamical systems approach to turbulence from the transitional regime to fully developed boundary layers.

8:26AM C11.00003 Heteroclinic and Homoclinic Connections in a Kolmogorov-Like Flow1, BALACHANDRA SURI, Institute of Science and Technology, Austria, RAVI KUMAR PALLANTLA, LOGAN KAGEORGE, MICHAEL F. SCHATZ, ROMAN O. GRIGORIEV, Georgia Institute of Technology, USA — Recent studies suggest that unstable recurrent solutions of the Navier-Stokes equation provide new insights into dynamics of turbulent flows. In this study, we compute an extensive network of dynamical connections between such solutions in a weakly turbulent quasi-two-dimensional Kolmogorov flow that lies in the inversion-symmetric subspace. In particular, we find numerous isolated heteroclinic connections between different types of solutions – equilibria, periodic, and quasi-periodic orbits – as well as continua of connections forming higher-dimensional connecting manifolds. We also compute a homoclinic connection of a periodic orbit and provide strong evidence that the associated homoclinic tangle forms the chaotic repeller that underpins transient turbulence in the symmetric subspace.

8:39AM C11.00004 Unstable Periodic Orbits in Experimental Kolmogorov-Like Flow1, LOGAN KAGEORGE, Georgia Inst of Tech, BALACHANDRA SURI, IST Austria, ROMAN GRIGORIEV, MICHAEL SCHATZ, Georgia Inst of Tech — The geometry of state space for a moderately turbulent flow is shaped by non-chaotic Navier-Stokes solutions known as Exact Coherent Structures (ECS). It has been shown in numerical studies of pipe flow that unstable periodic orbits, one such ECS, guide the evolution of nearby trajectories and form the backbone of the chaotic attractor. However, until now little experimental work has been done to show if periodic orbits are frequently visited in fluid systems and are therefore relevant to the dynamics of the system. We report on numerical work to identify periodic orbits and describe their dynamical relevance in experiments of weakly turbulent quasi-two-dimensional Kolmogorov-like flows.

8:52AM C11.00005 Experimental evidence of exact coherent structures in small-aspect-ratio Taylor-Couette flow1, CHRISTOPHER J. CROWLEY, Georgia Institute of Technology, MICHAEL C. KRYGIER, Sandia National Laboratories, WESLEY TOLER, ROMAN O. GRIGORIEV, MICHAEL F. SCHATZ, Georgia Institute of Technology — Recent work suggests that the dynamics of turbulent wall-bounded flows are guided by unstable solutions to the Navier-Stokes equation that have nontrivial spatial structure and temporally simple dynamics. These solutions, known as exact coherent structures (ECS), are presumed to play a key role in a fundamentally deterministic description of turbulence. Prior work in 3D fluid flows computed ECS in streamwise-periodic domains that differed from the inflow-outflow boundary conditions of corresponding experimental tests, which relied on the use of Taylor’s hypothesis to obtain laboratory measurements. Here we report evidence for ECS in a 3D turbulent flow by directly comparing experimental measurements with numerical simulations at the same parameter values and boundary conditions in a small-aspect-ratio (Γ = 1) turbulent Taylor-Couette flow with radius ratio η = 0.71. To detect an ECS, time-resolved 3D–3C velocity measurements were performed in the entire flow domain and compared to exact solutions of the Navier-Stokes equation obtained via fully-resolved direct numerical simulation.

9:05AM C11.00006 The mechanism of long turbulent lifetimes in a low-dimensional model of plane Couette flow. JAMES HITCHEN, ALEXANDER MOROZOV, SUPA, School of Physics and Astronomy, The University of Edinburgh, James Clerk Maxwell Building, Peter Guthrie Tait Road, Edinburgh, EH9 3FD, United Kingdom — Recently, our understanding of the transition to turbulence has significantly changed due to the discovery of exact solutions of the Navier-Stokes equations and the introduction of the self-sustaining process in parallel shear flows. This theory has been very successful in describing the main features of weakly turbulent states, including the metastable nature of turbulence close to the transition and the super-exponential dependence of its lifetime on the Reynolds number. The main strength of this approach is that it allows for a semi-analytical description of the turbulent dynamics in the form of a rather low-dimensional model. Here we systematically develop a novel low-dimensional model that allows us to investigate the origin of the very long turbulent life-times close to the transition. We find that there exists a particular periodic orbit that acts as a porous reflecting barrier between the laminar and turbulent states, and that serves to greatly increase the time before relaminarisation.

9:18AM C11.00007 Heteroclinic Connections as Predictors of Extreme Events in Weakly Turbulent Flow1. JOSHUA PUGHE SANFORD, ROMAN O. GRIGORIEV, Georgia Institute of Technology — Formally, extreme events occur in dynamical systems when an observable varies from its mean by many standard deviations. In practice, this describes events such as earthquakes, rogue waves, seizures, and heart attacks. Due to the catastrophic nature of these events on both an environmental and personal scale, an understanding of how these events occur is crucial. We investigate a two-dimensional Kolmogorov flow, where extreme events correspond to short-lived spikes in global dissipation. Using direct-adjoint iterations, we found a number of heteroclinic connections between unstable recurrent solutions characterized by very different rates in dissipation. We also found that extreme events correspond to the turbulent trajectories shadowing some of these connections in state space. These results suggest that heteroclinic connections may be used to understand and predict extreme events in this and other systems.

9:31AM C11.00008 Finding unstable periodic orbits with polynomial optimization, with application to a nine-mode model of shear flow1. MAYUR LAKSHMI, GIOVANNI FANTUZZI, Imperial College London, JESUS FERNANDEZ-CABALLERO, University of Warwick, YONGYUN HWANG, SERGEI CHERNYSHENKO, Imperial College London — It was recently suggested (Tobasco et al. Phys. Lett. A, 382, 382–386, (2018)) that trajectories of ODE systems which optimize the infinite-time average of an observable can be localized using sublevel sets of a function that arise when bounding such averages using so-called auxiliary functions. This talk will demonstrate that this idea allows for the computation of extremal unstable periodic orbits (UPOs) for polynomial ODE systems. We first show that polynomial optimization is guaranteed to produce near-optimal auxiliary functions, which are required to localize the extremal UPO accurately. We then show that points inside the relevant sublevel sets can be computed efficiently through direct nonlinear optimization. Such points provide good initial conditions for UPO computations. We illustrate the potential of this new technique of finding UPOs by presenting the results of applying it to a nine-dimensional model of a sinusoidally forced shear flow.

9:44AM C11.00009 The recurrence of flow structures in a low Re wake downstream of two cylinders1. HUIXUAN WU, MEIHUA ZHANG, University of Kansas, ZHONGQUAN ZHENG, Utah State University — The recurrence network method is used to study the evolution of coherent structures in the wake downstream of two cylinders. The upstream cylinder is fixed and the downstream cylinder oscillates in the transverse direction at a fixed frequency. The vortices shed from the upstream cylinder interact with those from the other cylinder, generating a complicated vorticity distribution. Proper orthogonal decomposition is used to extract coherent structures from the vorticity field, but the modes, which are spatial distributions of vorticity, provide limited information about the temporal evolution of the system. In order to analyze the evolution, the time dependent modal coefficients are used to construct a high dimensional phase space. The flow evolution is represented by a trajectory in this space. At the Reynolds number studied in this work, the system keeps visiting the neighborhood of a previous state, though it never exactly repeats itself. This kind of visit can be regarded as recurrence within a certain tolerance. The network manifests a few recurrence patterns, which corresponds to the ways of evolution of the flow field. The result shows that the recurrence network is an effective tool to analyze the temporal evolution of coherent structures.

Sunday, November 24, 2019 8:00AM - 10:10AM – Session C12 Vortex Dynamics and Vortex Flow: Wakes 303 - Diana Sher, University of Toronto

8:00AM C12.00001 Dr. forces on a bluff body shedding a 2P wake1. EMAD MASROOR, MARK A. STREMLER, Virginia Tech — We develop analytical expressions for the drag experienced in a uniform flow by a bluff body shedding a 2P wake. Following von Karman’s well-known method for the drag experienced by a fixed cylinder with a typical ‘von Karman street’-type wake, we set up a potential flow past a general bluff body and model its wake as an infinite periodic collection of point vortices with 4 vortices per period. The relative positions of the 4 vortices are calculated by determining the relative equilibrium configurations of 2P wakes. By considering the momentum flux into and out of a rectangular region enclosing the body and cutting through the wake, we determine the drag forces exerted on the cylinder over one period of vortex shedding. The drag coefficients predicted by this method will be compared to those predicted for objects shedding a standard von Karman street, giving insight into the effect of wake type on the drag.

8:13AM C12.00002 2P or not 2P? , JASON DAHL, ERDEM AKTOSUN, University of Rhode Island — The characterization of modes in the wake of an oscillating cylinder in a free stream has become a common method for describing the spatial variation of vorticity and coherent vortices in these wakes. Arguably, the most commonly observed wake modes come from the classification of Williamson and Roshko (1989) for a cylinder oscillating in the crossflow direction with definitions such as ‘2S’ to describe two single vortices shed per cycle of motion and ‘2P’ to describe two pairs of opposite rotating vortices shed per cycle. When a cylinder is allowed to move in both the in-line and cross-flow direction, however, these simplified classifications of the wake become muddled, as the phasing and pinch-off of vortices can result in intermediate wakes that might fall in between typically observed wake modes, form new complex combinations of vortices, or form strongly three-dimensional wakes with little coherent vortex structure in a 2-D plane. Through a series of forced motion experiments of a circular cylinder undergoing forced in-line and cross-flow motion in a free stream, this complex wake variability is demonstrated, with focus particularly on formation of the ‘2P’ mode, leading to the question: 2P or not 2P?
8:26AM C12.00003 Optimization of mangrove-root inspired arrangements for minimizing wake disturbances. AISHWARYA S. NAIR, AMIRKHOSRO KAZEMI, OSCAR M. CURET, SIDDHARTH VERMA, Florida Atlantic University — Coastal protection measures such as seawalls are vital for reducing the impact of storms and risk of flooding. The root systems of red mangroves, which are a part of certain coastal ecosystems, provide a natural barrier that dissipates wave energy effectively. The replication of such systems could benefit the design of coastal protection infrastructure substantially. In this work, we present simulations of flow across arrays of circular cylinders, as a simplified model of the root network. The objective is to determine the optimal root arrangements that minimize the disturbances in their wake. We couple these simulations with a genetic optimization algorithm, NSGA II, to discover the optimal configurations that generate the least entrainment in their wake. The configurations that produce the highest and lowest entrainments were studied experimentally using Particle Imaging Velocimetry, and a soap film setup. The resulting flow patterns are analyzed to relate the increase or decrease in wake-disturbance to interactions among vortices shed at the individual cylinder level within the arrangements.

8:39AM C12.00004 Vortex Shedding Dynamics for Nonparallel Tandem Cylinders. DIANA SHER, SEAN BLANEY, PHILIPPE LAVOIE, University of Toronto — Nonparallel tandem cylinder geometries are found in many industrial applications. This type of geometry can lead to significant flow induced vibration and noise emissions. However, the flow dynamics is not well understood since this geometry has not received as much attention as isolated or parallel tandem cylinders. This work considers an upstream circular cylinder perpendicular to the flow and a yawed downstream cylinder. Measurements were conducted in an open jet anechoic wind tunnel (AWT) at UTIAS. Yaw angles up to 45° over a range of Re = 40,000-120,000 were tested. The vortex shedding behavior along the span of the cylinders was investigated using surface pressure measurements. Peak patterns observed in the spectra indicate the presence of spanwise-dependent flow cells. A single dominant peak in the frequency spectrum exists where the spacing between the cylinders is narrow, two prominent peaks appear at intermediate spacings, and at locations where the spacing is wide, a single peak is present. There are two distinct shedding frequencies at which these peaks occur for each yaw angle, suggesting the existence of two flow cells. The shedding frequency increases for larger yaw angles independently of Re, with the lower frequency peak exhibiting a larger shift.

8:52AM C12.00005 Wake mode variability for a circular cylinder in a free stream with force sinusoidal in-line and cross-flow motion. ERDEM AKTOSUN, JASON DAHL, University of Rhode Island — Quantitative flow visualization and force measurements were systematically obtained for a circular cylinder undergoing forced sinusoidal in-line and cross-flow motion in a free stream. Variation of the in-line amplitude, cross-flow amplitude, reduced velocity, and phase between in-line and cross-flow motions were made for a fixed Reynolds number of 7620, with a total of 819 experiments for flow visualization and 9555 for force measurements. Visual categorization of the wake shows a wide variability in pattern of vortices shed in the wake, resulting in a wide variability in the resultant forces acting on the cylinder. Although all motions are symmetric in the cross-flow direction, some parameter combinations are observed to produce an asymmetric wake and strong mean lift forces. For a simple demonstration of the complex variation of the wake, one example baseline motion is shown, where small perturbations from the baseline motion are given to demonstrate wake changes as a function of the motion parameters.

9:05AM C12.00006 Vortex-Induced Vibrations of a One-Degree-of-Freedom Cylinder Transitioning from the Inline to the Transverse Degree of Freedom. BRIDGET BENNER, YAHYA MODARRES-SAEDEGH, University of Massachusetts Amherst — Flow-induced oscillations of a cylinder with one degree of freedom in the purely inline direction, and at angles that deviate from the inline direction, are studied experimentally. Experiments are conducted in a recirculating water tunnel using a setup with a low mass-damping coefficient. Force and displacement measurements together with flow visualization of the wake are used to characterize the response of the cylinder over a range of reduced velocities as the single degree of freedom incrementally deviates from the inline direction. It is shown that the two non-zero amplitude regions that are observed at reduced velocities of 1.8 and 2.5 in a purely inline vortex-induced vibration (VIV) response of the cylinder slowly disappear as the angle is increased and the lock-in region, usually observed in a pure crossflow VIV response, appears at higher angles. It is also shown how the observed vortex shedding modes change as the degree of freedom deviates from a pure inline direction.

9:18AM C12.00007 Pulsating Flow Past a Square Cylinder at Low Reynolds Number: Analysis of Vortex Structures. THOMAS FOWLER, IV, FREDDIE WITHERDEN, SHARATH GIRIMAJI, Texas A&M University — Flow past a fixed square cylinder is a canonical problem for investigating vortex-induced vibration and various wake flow physics of interest to several engineering fields. A variant of this problem is that of a pulsating inflow condition. In this work, direct numerical simulations were performed for the case of pulsating flow at Re = 200 over a range of forcing frequencies. As in literature, three regimes are identified: (i) Pre-Lock-in; (ii) Lock-in; and (iii) Post-Lock-in. In Pre-Lock-in, vortex shedding is asymmetric and aperiodic, with the shedding frequency matching that of the uniform case. During Lock-in, vortex shedding remains asymmetric, but becomes distinctly periodic owing to the synchronization of the detachment of the primary and secondary vortices. Here the vortex shedding frequency is determined by the forcing frequency, leading to an increase in the forces experienced by the body. Transitioning to Post-Lock-in, the increasingly strong pulsations lead to symmetric detachment of the primary vortices, disrupting the asymmetric shedding of secondary vortices, and returning to aperiodicity. Spectral analysis then provides further insight regarding the sharp transition into the lock-in regime as opposed to the gradual transition beyond.

9:31AM C12.00008 Effect of Eliminating Trailing Edge Vortices on Thrust Coefficient in a Plunging Flat Plate. AVELINA RAHMAN, PhD Student, DANESH TAFTI, Professor — Plunging motion, characterized by frequency and amplitude is a key component in the kinematics of many flying and swimming organisms. We studied plunging of a flat plate with a broad range of reduced frequencies 0.25 ≤ k ≤ 16 and plunge amplitudes 0.03125 ≤ h ≤ 0.1 giving plunge velocities of 0.25 ≤ k h ≤ 5 at Re=100. This study observed that, unlike previous investigations for small plunge amplitudes, thrust does not increase monotonically with kh but reaches a maximum and then decreases. It is shown that Leading Edge Vortices (LEV) are responsible for thrust production whereas Trailing Edge Vortices (TEV) induce drag on the plate. At higher kh, vortex induced velocities dominate the flow with strong nonlinear vortex-vortex interactions (VVI). Three main VVI mechanisms are identified: in two of them TEV adversely affect thrust production. It is shown that by introducing a splitter plate that eliminates the formation of TEVs, the thrust coefficient (C_T) increases monotonically with kh. A parametrization of the thrust coefficient is done with frequency (k) and amplitude (h) C_T = A k^{1.4} h - B where A and B are constants, with a R^2 =0.96 for the proposed equation. Additionally, a scaling analysis is done between C_T and circulation to see the effect of eliminating TEV on LEV dynamics.
9:44AM C12.00009 Sparse sensor placement for machine learning classification of pitching and plunging plates, JONATHAN TU, NSWC Carderock — We consider the task of using downstream measurements to characterize the upstream motion of a rigid flat plate, which can be thought of as a simplified model of a swimming fish. Specifically, we numerically simulate pitching and plunging plates at a Reynolds number of 100, then apply Linear Discriminant Analysis (LDA) to distinguish between the two upstream motions. To reduce the dimension of the feature space, we apply LDA to projection coefficients of the flow field obtained using proper orthogonal decomposition (POD). However, at inference time this still requires collecting full flow field data, in order to perform the POD projection. To avoid having to collect full flow fields at all, we also use the Sparse Sensor Placement Optimization for Classification (SSPOC) algorithm to find a small number of point sensors that provide the same information as a POD projection. We implement both the original algorithm and a new extension of SSPOC for vector-valued measurements. Whereas the standard SSPOC algorithm might choose certain sensor locations for the \( u \) velocity and others for the \( v \) velocity, our vector SSPOC algorithm places sensors for \( u \) and \( v \) at the same locations. Classification using either SSPOC variant achieves similar accuracy to that using full flow field data.

9:57AM C12.00010 Dynamics of wing tip vortices in the near and far wake, MARIE COULIOU, KEVIN AZIM, JEAN-CLAUDE MONNIER, VINCENT BRION, DAAA, ONERA, ONERA TEAM — Wing tip vortices are a major challenge for civil aviation, both regarding air transport management (efficiency, safety) and environmental impact (induced drag, condensation trails). In this work, an experimental investigation on the development of cooperative instabilities of vortex wakes in the near and far field of a finite wing is carried out. The experiment takes place in a 22 m long hydrodynamic towing tank capable of towing speeds up to 5 m/s and enabling PIV measurements up to 200 spans of wake development. PIV data provides an extensive characterization of the vortex evolution. The effect of a perturbation placed along the span of the wing, following recent theoretical results on the control of vortex wake dynamics, is particularly discussed.

Sunday, November 24, 2019 8:00AM - 9:57AM – Session C13 Convection and Buoyancy-driven Flows: Environmental Flows 304 - Nigel Kaye, Clemson University

8:00AM C13.00001 Flow structures and kinetic-potential energy exchange in forced rotating stratified turbulence, TIANYI LI, Peking University, MINPING WAN, JIANCHUN WANG, SHIYI CHEN, Southern University of Science and Technology — We investigate the long-time evolution of flow structures and the kinetic-potential energy exchange \( e_{K\text{to}P} \) in rotating stratified turbulence. Numerical simulations of forced homogeneous rotating stratified turbulence with different Froude numbers are performed. In the presence of stratification, with two box scale structures with opposite signs of vertical vorticity formed at later times, there are numerous small vortices spreading in the flow. Cyclonic vortices, though being less numerous than anticyclonic vortices, grow faster, thus forming the box-scale structure earlier. Moreover, the intense area of \( e_{K\text{to}P} \) is associated with the cyclonic structures. We also find a relation between vertical vorticity and the distribution of the density in the vortices during the evolution of turbulence.

8:13AM C13.00002 Prandtl Number Dependence of Stratified Turbulence, JESSE LEGASPI, MICHAEL L. WAITE, University of Waterloo — Stratified turbulence is affected by buoyancy forces that suppress vertical motion, resulting in horizontal layers of quasi-two-dimensional vortices. The Prandtl number \( Pr \) (or Schmidt number) quantifies the relative strengths of viscosity and buoyancy diffusivity which damp small-scale fluctuations at different microscales. Direct numerical simulations (DNS) must resolve the smallest features, requiring high resolution for large \( Pr \) (e.g. \( Pr = 7 \) in heat-stratified water and 700 in salt-stratified water). To reduce this computational demand \( Pr = 1 \) is often assumed, possibly introducing discrepancies between DNS and real geophysical flows. In this work, DNS of homogeneous forced stratified turbulence with \( Pr = 0.7, 1, 2, 4, \) and 8 are performed for varying stratification strength. Energy spectra, buoyancy flux spectra, spectral energy flux, and physical space fields are compared for scale-specific \( Pr \)-sensitivity. Intermediate and large scale \( Pr \)-dependence was found in addition to expected small-scale sensitivity. Based on our results, the \( Pr = 1 \) assumption is not realistic for DNS of \( Pr > 1 \) stratified turbulence: the effects at intermediate, and in some cases, large horizontal scales must be considered, though the computational demand can be prohibitive.

8:26AM C13.00003 Examination of temperature spectra in stably stratified boundary layers measured using nano-scale probe, FIONA SPENCER, University of Washington, TYLER VAN BUREN, University of Delaware, ALEXANDER J SMITS, Princeton University, OWEN WILLIAMS, University of Washington — Thermally stable turbulent boundary layers are prevalent in the polar regions and nocturnal atmospheric surface layer but measurements are challenged by changing conditions and small fluxes. Here, we examine the influence of increasing stratification on the spectrum of temperature fluctuations in a laboratory-scale boundary layer over a rough surface. A nanoscale cold-wire (T-NSTAP) is employed to significantly increase frequency response and resolution compared to conventional cold-wires. This method is used to examine boundary layer conditions from near-neutral, through to the collapse of turbulence. This novel dataset allows examination of changes to temperature spectra, their energy cascade and wall-normal locations of maximum spectral energy in both inner and semi-local coordinates. These results when compared to atmospheric data, provide insights into the separation of Reynolds and Richardson number influences.
8:39AM C13.00004 Dynamics of subsiding shells in actively growing clouds with vertical updrafts, VISHNU NAIR, Imperial College London — The dynamics of a subsiding shell at the edges of actively growing shallow cumulus clouds with updrafts is analyzed using direct numerical simulations with grid sizes up to 3072 x 1536 x 1536. The actively growing clouds have a fixed in-cloud buoyancy and velocity. Turbulent mixing and evaporative cooling at the cloud edges generate a subsiding shell which grows with time. A self-similarity analysis reveals that contrary to classical self-similar flows, the turbulent kinetic energy budget terms and the velocity moments scale according to the buoyancy and not with the mean velocity. The shell accelerates ballistically with a magnitude dependent on the saturation value of the buoyancy of the cloud-environment. Tint influence. In this regime, the shell is buoyancy-driven and independent of the in-cloud velocity. The shell thickness and the velocity continue to grow indefinitely and could possibly be limited only by the lifetime of the cloud or thermal. The entrainment coefficient is observed to be a function only of the initial state of the cloud and the environment. This coefficient is linked to the fractional entrainment rate used in cumulus parameterization schemes for large scale models and is shown to be of the same order of magnitude.

8:52AM C13.00005 Impact of ambient stratification on gravity currents propagating over a submerged canopy, JIAN ZHOU, University of California, Berkeley, S. KARAN VENAYAGAMOORTHY, Colorado State University — The dynamics of lock-exchange gravity currents propagating over a submerged canopy in a linearly stratified environment is investigated using highly resolved three-dimensional large-eddy simulations. The canopy is composed of a bottom-mounted array of square cylinders. It is highlighted that the structure and propagation of the gravity currents show remarkable variation across the parameter space of canopy density and ambient stratification. For sparse canopies, the gravity current propagates through the canopy interior, and the reduction in front speed is less sensitive to the canopy drag under stronger ambient stratification where there is less wake-induced buoyancy loss of the current head. For denser canopies, the transition to over-flow on the canopy top and the accompanied recovery of front speed are found to occur earlier in canopy density as the ambient stratification becomes stronger, which is the outcome of three mechanisms: (i) weaker canopy drag due to the altered propagation pathway; (ii) less convective mixing of the over-head with the underlying lighter fluid; and (iii) more regain of effective horizontal buoyancy gradient as the current is lifted up. The latter two mechanisms occur due to the background stratification.

9:05AM C13.00006 Computational modeling of dense gas flushing from urban canyons, RASNA SHARMIN, NIGEL KAYE, Clemson University — Results are presented from a series of CFD simulations of the flushing of a dense pollutant from a model urban canyon. The simulations are run using both RANS and LES simulations for the flushing from a square canopy formed between two square prismatic buildings. Results are presented for the flushing rate for a range of Richardson numbers with higher Richardson number flows exhibiting lower flushing rates. The influence of the upstream surface roughness, formed by imposing a saw-tooth geometry of various aspect ratios on the flow floor, elucidate the role of the boundary layer structure on the flow over the canyon and resulting flushing rate. The computational results are compared to prior experimental results for the same geometry with the goal of further elucidating the flow structure under more controlled conditions.

9:18AM C13.00007 Coaxial moist plumes in stationary and windy environments1, SHUO LI, MORRIS FLYNN, Department of Mechanical Engineering, University of Alberta, Edmonton, AB T6G 1H9 — We report on the dynamics of coaxial plumes in both stationary and windy ambient environments. The coaxial plumes consist of hot, humid air as the inner, circular plume, and warm, less humid air as the outer, annular plume. For a stationary ambient, a double plume model is proposed using a three-way entrainment formulation that involves three undetermined entrainment coefficients. Two body force formulations are discussed, which regard either the ambient or the outer plume as the reference fluid for the inner plume. Meanwhile, a planar laser-induced fluorescence (PLIF) technique is employed to visualize the flow and quantify the scalar concentration of either the inner or outer plumes. The PLIF experiment reveals different near-field entrainment behaviors for cases wherein the inner plume is more/less buoyant than the outer plume. Moreover, the optimal values for the entrainment coefficients are determined by a pixel-by-pixel comparison of the scalar concentration between theory and experiment. For a windy ambient, theoretical results show that wind tends to rapidly dilute the heat and moisture transferred from the inner to the outer plume.

9:31AM C13.00008 Large-scale and Small-scale Turbulent Structures in a Stably Stratified Shear Layer1, TOMOAKI WATANABE, Nagoya University, JAMES J. RILEY, University of Washington, KOJI NAGATA, Nagoya University, KEIICHI MASUDA, RYO Q NISHI, JAMSTEC — Title: Large-scale and Small-scale Turbulent Structures in a Stably Stratified Shear Layer Turbulent structures in a stably stratified shear layer are investigated with direct numerical simulations (DNS). Initial mean streamwise velocity and density are given by hyperbolic tangent functions and, therefore, shear and stratification are localized in a thin layer with an initial thickness of \( h_0 \). The DNS uses a very large computational domain in horizontal directions. The Reynolds number and Richardson number based on \( h_0 \) and the density and velocity differences across the shear layer are 2000 and 0.06, respectively. Turbulence develops from the initial conditions, grows, and then it rapidly decays with time. Flow visualization employing the second invariant of the velocity gradient tensor confirms that a large number of hairpin vortices appear near the edge of the shear layer at late time in the simulation. Very elongated flow structures are also found for the streamwise velocity visualized on a horizontal plane, where the length of these long structures is about 10 times larger than the shear layer thickness. It is also shown that the length scales associated with the hairpin vortices and the elongated flow structures make large contributions to turbulent kinetic energy.

9:44AM C13.00009 On Correlations of Lagrangian and Eulerian Accelerations in Turbulent Stratified Shear Flows, FRANK JACOBITZ, University of San Diego, KAI SCHNEIDER, Aix-Marseille University — The correlations of Lagrangian and Eulerian accelerations of homogeneous turbulence with uniform shear and stratification are investigated using data from direct numerical simulations. In order to vary the relative importance of shear and stratification, a Richardson number range from \( R_i = 0 \) corresponding to unstratified shear flow, to \( R_i = 10 \), corresponding to strongly stratified shear flow, is considered. The correlations between Lagrangian and Eulerian accelerations are observed to increase with increasing Richardson number. Using a wavelet-based scale decomposition of the acceleration signals at different scales, further investigated. It was found that the Lagrangian and Eulerian accelerations are strongly correlated at large, energy-containing scales of motion. However, the correlations decrease with decreasing scale of the turbulent motion and the accelerations are mainly decorrelated at small, dissipative scales of motion. In addition, the correlations of Lagrangian and Eulerian time-rates of change of fluctuating density are also considered. Again, stronger correlations are obtained at larger Richardson numbers and at larger scales of the turbulent motion.
A comparative experimental and numerical study of rotating Rayleigh-Bénard convection in a cylindrical cell

We acknowledge funding from the H2020 European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (grant number 678634).

Large Scale Vortices in the Rotating Rayleigh-Bénard setup with no-slip boundaries

Probing Regimes and Transitions in Rapidly Rotating Rayleigh-Bénard Convection

We acknowledge funding from the H2020 European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (grant number 678634).

Effects of Lateral Confinement on Rapidly Rotating Rayleigh-Bénard Convection

We acknowledge funding from the H2020 European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (grant number 678634).
8:52AM C14.00005 Heat transport by rotating Rayleigh-Bénard convection in cylindrical cells with various aspect ratios1. JIN-QIANG ZHONG, HAO-YUAN LU, JUN-QIANG SHI, Tongji University — Rotating convection has been of interest for decades, yet there exists no generally accepted scaling law for heat transfer behavior in the geostrophic turbulence regime. We present high-precision measurements of the Nusselt number Nu as functions of the Rayleigh number Ra and the Ekman number Ek using cylindrical cells with various aspect ratio Γ. For a given Γ data for Nu(Ra(Ek)) in the geostrophic regime can be represented through one single power function Nu=(Ra/Rac)γ, where Rac=8.7Ek−4/3 is the critical Ra for the onset of convection. However, our experimental and numerical results reveal that the exponent γ increases steeply with increasing Γ, leading to various parameter scaling for the transition towards the geostrophic regime. The present study may provide hints to reconcile previous results of the heat-transport scaling relationship in geostrophic turbulence.

9:05AM C14.00006 Rigorous and numerical upper bounds on heat transport in rapidly rotating Rayleigh-Bénard convection. JARED WHITEHEAD, BENJAMIN PACHEV, Brigham Young University — We present recent rigorous and numerical upper bounds on the heat transport for rapidly rotating Rayleigh-Bénard convection using the asymptotically derived non-hydrostatic quasi-geostrophic equations. We also discuss the challenges inherent to developing upper bounds in the presence of rapid rotation, and propose some novel approaches to the same.

9:18AM C14.00007 Centrifugal Buoyancy and Non-Boussinesq Heat Transfer in Rotating Rayleigh-Bénard Convection1. JONATHAN CHENG, University of Rochester, SIETZE OOSTVEEN, MATTEO MADONIA, RUDIE KÜNNEN, Eindhoven University of Technology — In laboratory experiments of rotating Rayleigh-Bénard convection, conditions differ from the idealized problem in several significant ways. Important among these differences are the presence of centrifugal buoyancy — which causes colder fluid to be driven radially outward and is characterized by the Froude number (Fr) — and non-Boussinesq effects — where variations in the fluid properties break the vertical symmetry of the temperature field. Here, we present a suite of rotating convection simulations under fixed heat flux and Coriolis influence, but with varying centrifugal forcing. The heat transfer is suppressed as Fr increases, with the transition occurring in agreement with the force balance arguments of Horn & Aurnou, Phys. Rev. Lett. 120:204502, 2018. We compare the influence of centrifugation with that of non-Boussinesq effects by examining sidewall temperature gradients in the TROCONVEX rotating convection lab setup. At the sidewall, we expect these two effects to compete against one another. When the Rayleigh number is increased we observe the expected positive shift in the midplane temperature (Ahlers et al., J. Fluid Mech. 596:409-445, 2006), and when Fr is increased, the positive shift is present but reduced.

1This project is funded by the European Research Council (ERC) under the European Union’s Horizon 2020 research and innovation programme (grant agreement no 678634).

9:31AM C14.00008 Boundary Zonal Flow (BZF) in rotating turbulent convection. EBERHARD BODENSCHATZ, XUAN ZHANG, Max Planck Institute for Dynamics and Self-Organization, DENNIS VAN GILS, University of Twente, SUSANNE HORN, Coventry University, MARCEL WEID, LUKAS ZWIRNER, Max Planck Institute for Dynamics and Self-Organization, GUENTER AHLERS, University of California at Santa Barbara, ROBERT ECKE, Los Alamos National Laboratory, STEPHAN WEISS, OLGA SHISHKINA, Max Planck Institute for Dynamics and Self-Organization, INTERNATIONAL COLLABORATION FOR TURBULENCE RESEARCH COLLABORATION — We report the discovery and overall properties of a wall-localized mode of turbulent, rotating Rayleigh-Bénard convection, denoted as a boundary zonal flow (BZF). The BZF is characterized by the Froude number (Fr) and non-Boussinesq effects — where variations in the fluid properties break the vertical symmetry of the temperature field. Here, we present a suite of rotating convection simulations under fixed heat flux and Coriolis influence, but with varying centrifugal forcing. The heat transfer is suppressed as Fr increases, with the transition occurring in agreement with the force balance arguments of Horn & Aurnou, Phys. Rev. Lett. 120:204502, 2018. We compare the influence of centrifugation with that of non-Boussinesq effects by examining sidewall temperature gradients in the TROCONVEX rotating convection lab setup. At the sidewall, we expect these two effects to compete against one another. When the Rayleigh number is increased we observe the expected positive shift in the midplane temperature (Ahlers et al., J. Fluid Mech. 596:409-445, 2006), and when Fr is increased, the positive shift is present but reduced.

9:44AM C14.00009 Properties of the Boundary Zonal Flow (BZF) in rapidly rotating turbulent convection1. XUAN ZHANG, LUKAS ZWIRNER, Max Planck Institute for Dynamics and Self-Organization, SUSANNE HORN, Coventry University, DENNIS VAN GILS, University of Twente, MARCEL WEID, Max Planck Institute for Dynamics and Self-Organization, GUENTER AHLERS, University of California at Santa Barbara, STEPHAN WEISS, EBERHARD BODENSCHATZ, Max Planck Institute for Dynamics and Self-Organization, ROBERT ECKE, Los Alamos National Laboratory, OLGA SHISHKINA, Max Planck Institute for Dynamics and Self-Organization, INTERNATIONAL COLLABORATION FOR TURBULENCE RESEARCH COLLABORATION — Properties of the boundary zonal flow (BZF) in rapidly rotating Rayleigh-Bénard convection are investigated numerically. Based on direct numerical simulations (DNS) using the finite-volume code GOLDFISH, we analyze in detail the BZF and, in particular, the traveling-mode structures and their dependencies on Ekman number. We also investigate the role of the BZF in the global heat transport in the system as well as the influence of the Prandtl number and the aspect ratio of the cylindrical convection cell on the BZF properties.

1The work is supported by Max Planck University Twente Center for Complex Fluid Dynamics, Los Alamos National Laboratory (LDRD program), Deutsche Forschungsgemeinschaft (SFB963, SPP1881, Sh405/4-1, Sh405/4-2, Sh405/7-1, Sh405/8-1, Ho5890/1-1, We5011/3-1).
9:57AM C14.00010 Experimental investigation of the Boundary Zonal Flow (BZF) in rotating turbulent convection1, STEPHEN WEISS, Max Planck Institute f. Dynamics and Self-Organisation, DENNIS VAN GILS, University Twente, MARCEL WEDI, XUAN ZHANG, Max Planck Institute f. Dynamics and Self-Organisation, SUSANNE HORN, Coventry University, LUKAS ZWIRNER, Max Planck Institute f. Dynamics and Self-Organisation, ROBERT ECKE, Los Alamos National Laboratory, OLGA SHISHKINA, Max Planck Institute f. Dynamics and Self-Organisation, GUENTER AHLERS, University of California, Santa Barbara, EBERHARD BODENSCHATZ, Max Planck Institute f. Dynamics and Self-Organisation, INTERNATIONAL COLLABORATION FOR TURBULENCE RESEARCH (ICTR) COLLABORATION — We report on measurements in rotating turbulent Rayleigh-Bénard convection, in a 2.20 m high cylindrical cell of aspect ratio between its diameter and height of $\Gamma = 1/2$. The working fluids are nitrogen and pressurized (up to 19 bar) sulfur hexafluoride ($\text{SF}_6$). We cover a large Rayleigh number range of $5 \times 10^9 \leq Ra \leq 5 \times 10^{12}$ at Prandtl numbers in the range $0.74 \leq Pr \leq 0.96$. Using thermal probes close to the cylindrical sidewalls we measure characteristic properties of the recently found boundary zonal flow (BZF) as a function of $Ra$ and the rotation rate, i.e., the inverse Rossby number ($1/Ro$). We also discuss in our talk the influence of the BZF on the heat transport.

The work is supported by Max Planck University Twente Center for Complex Fluid Dynamics, Los Alamos National Laboratory (LDRD program), Deutsche Forschungsgemeinschaft (SFB903, SPP1881, Sh405/4-1, Sh405/4-2, Sh405/7-1, Sh405/6-1, Ho5880/1-1, Wi6011/3-1).

Sunday, November 24, 2019 8:00AM - 10:10AM — Session C15 Turbulence: Mixing 310 - Nathanael Machicoane, University of Washington

8:00AM C15.00001 Scalar power spectra and turbulent length scales in high-Schmidt-number scalar fields, MOHAMMAD MOHAGHAR, Georgia Institute of Technology, LAKSHMI P DASI, The Ohio State University, DONALD R WEBSTER, Georgia Institute of Technology — This experimental study has investigated effects of Reynolds number ($5000 \leq Re \leq 20,000$) and initial release diameter ($2.2\text{mm} \leq D \leq 9.4\text{mm}$) on scalar power spectra and turbulent length scales of high-Schmidt-number passive scalar fields resulting from an iso-kinetic release in a turbulent boundary layer. The turbulence analysis is based on 12,000 scalar fields collected using the PLIF technique for each case at 6 locations downstream. Although the spectral slope at intermediate scales is found to increase to an asymptotic value higher than $-5/3$ farther downstream, there is an increase in spectral slope from approximately $-1.5$ for $Re = 5000$ to roughly $-1.2$ for $Re = 20,000$ while fixing the release diameter at 4.7 mm. A similar trend is observed for the effect of nozzle diameter on spectral slope, as it increases from almost $-1.5$ to $-1.2$ when the nozzle diameter changes from 9.4 mm to 2.2 mm while fixing $Re = 10,000$. The scalar integral scale and scalar Taylor microscales are calculated directly from the scalar fields using the correlation function. It was found that the Taylor microscale decreases and the integral scale increases to an asymptotic value respectively, farther downstream. This indicates a larger range of scales exists as flow becomes more turbulent.

8:13AM C15.00002 Frozen waves in turbulent mixing layers, BENOIT-JOSEPH GREA, CEA — Strong time-periodic accelerations applied tangentially to an infinite horizontal plane layer between two miscible fluids trigger a parametric instability leading to remarkable saw-tooth patterns known as frozen waves. The resulting turbulent mixing zones grow in time and then saturate when the resonance conditions of internal gravity waves are no longer fulfilled. The Floquet analysis of a model equation and direct numerical simulations reveal that the final mixing zone sizes evolve as the square of the forcing amplitude while, by contrast, the horizontal wavelengths grow nearly linearly. This explains why frozen waves sharpen with increasingly intense horizontal oscillations. It also suggests that an horizontal forcing mixes more efficiently fluids than a vertical one at large forcing accelerations.

8:26AM C15.00003 Complex network-based Lagrangian analysis of turbulent mixing in channel flows at different Reynolds numbers, GIOVANNI IACOBELLO, STEFANIA SCARSOGLIO, Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Turin, Italy, HANS KUERTEN, Department of Mechanical Engineering, Eindhoven University of Technology, Eindhoven, The Netherlands, LUCA RIDOLFI, Department of Environmental, Land and Infrastructure Engineering, Politecnico di Torino, Turin, Italy — Turbulent mixing is a fundamental issue in many applications, from natural phenomena to industry. In the Lagrangian viewpoint, typical investigations involve the temporal evolution of pairwise mean-square separation or multi-particle shape evolution. In this work, recent advances in complex networks are exploited to study turbulent mixing in a Lagrangian framework. The dynamics of a set of fluid particles is geometricized in a time-dependent complex network, in which nodes correspond to groups of particles and link activation is based on particle spatial proximity. A turbulent channel flow setup is considered at different Reynolds numbers, with the aim to highlight the relative intensity of advection and mixing. Specifically, accurate direct numerical simulations of turbulent channel flows are performed, with Reynolds number between 180 and 950. By doing so, the network-based approach is able to capture the temporal development of particle dynamics due to the turbulent motion, as well as transient and long-term features of wall-normal turbulent mixing. Based on present findings, Lagrangian-based networks can pave the way for a systematic network-based investigation of turbulent mixing, thus extending the level of information of classical statistics.

8:39AM C15.00004 Alignment Analysis of Passive Scalar Mixing in Shock Turbulence Interaction, XIANGYU GAO, IVAN BERMEJO-MORENO, University of Southern California, JOHAN LARSSON, University of Maryland — The transport of passive scalar fields by an initially isotropic turbulent flow passing through a nominally planar shock wave is investigated via shock-capturing DNS for different Mach numbers (1.5 to 5), turbulence Mach numbers (0.1 to 0.4), and Taylor microscale Reynolds numbers (40, 70), with unitary Schmidt number, including both wrinkled- and broken-shock regimes. The effects of the shock-turbulence interaction on alignments between the strain-rate eigenvectors and vorticity, scalar gradient, and the mean streamwise direction are studied, aided by a novel barycentric map representation. Across the shock, the scalar gradient shows an increased alignment with the most extensive eigenvector of strain rate at the expense of a reduced alignment with the most compressive eigenvector (which still dominates) and with the intermediate eigenvector (which becomes nearly perpendicular). This trend is more obvious with larger Mach number and smaller Taylor microscale Reynolds number. Also, across the shock, the most probable alignment between the passive scalar gradient and the eigenvectors of the strain-rate tensor is found to converge towards the alignment that provides the largest scalar dissipation, which is correlated with the enhanced scalar mixing observed downstream of the shock.
A Fractional-Order Non-Fickian Transport Model For Scalar Turbulence

The influence of propagation angle on vortex ring-induced mixing

The largest Schmidt number ratio considered is 64, occurring between two scalars of $Sc = 4$ and 256, whose fluctuations are produced by velocity fluctuations acting upon a uniform mean scalar gradient. Spectral transfer characteristics examined individually for each scalar show robust evidence of a forward cascade, where local transfer by nonlocal interactions modulated by low-wavenumber velocity modes is readily observed at the small scales. Contributions to the coherency spectra from m Molly scalar-non-local velocity-scalar triads were found to produce a net decorrelating effect at small scales which is balanced by the coherent mean gradient forward cascade leading to a stationary state. The scalings of the two-scalar difference spectrum and joint dissipation rate are investigated in detail. The role of differential diffusion in double-diffusive convection is briefly addressed.

EPSRC
8:00AM C16.00001 An h-adaptive immersed boundary method for simulating fluid-structure interaction. PAN ZHANG, Institute of Applied Physics and Computational Mathematics — Fluid-structure interaction (FSI) problems are encountered in many scientific and engineering applications. As an important calculation model in the field of computational fluid dynamics, immersed boundary method is commonly used to deal with FSI problems. And the method has a wide range of applications. However, for FSI of moving boundary problems for large-scale motion, the moving boundary problem of large-scale motion, the immersed boundary method on uniform grid or non-uniform grid has limitations. This work combines the flexibility of adaptive mesh refinement methods, specifically for uniform Euler mesh. Based on the common characteristics of these two methods, the adaptive mesh refinement method is applied to the immersed boundary method and an adaptive immersed boundary method is presented to adapt to the calculation of the moving boundary problem of large-scale motion.

8:00AM C16.00002 Flow-Structure Interaction Simulation of Parachute using Immerged Boundary Method with Implicit Aerodynamical Load. HANG YU, CARLOS PANTANO, University of Southern California, FEHMI CIRAK, University of Cambridge — A method of flow-structure interaction simulation of the thin structure is presented. The immersed boundary method is used to incorporate the dynamics of the fluid and thin structure. A Cartesian background grid is used for compressible flow simulation and the thin structure is represented by Lagrangian markers immersed in the fluid. Linear operators based on the delta function is used for the interpolation and spreading. The boundary condition is enforced with a singular force \( f \) that is supported on the thin shell \( S \) which serves as boundary representation. Analog to the projection method for incompressible flow, the singular force is regarded as a Lagrangian multiplier to enforce boundary condition. A splitting method is used. The singular force is calculated implicitly by solving a symmetric system, which scales as number of Lagrangian markers. Furthermore, with the interpolation operator acting on the momentum equation, the implicit singular force can be subsequently translated as the aerodynamical load for the thin shell. Therefore, separate calculation of pressure and viscosity load is no longer needed. Lagrangian markers are dynamically removed or added to prevent leakage, unphysical oscillation, or the implicit force equation being underdetermined.

8:26AM C16.00003 An Immersed Boundary Formulation for Fluid-Structure-Interaction in Multi-phase Flows. ELIZABETH GREGORIO, AKASH DHRUV, MEGAN C. LEFTWICH, ELIAS BALARAS, George Washington University — Immersed boundary methods have been widely used to study single-phase flow problems involving complex geometries. However, the extension of existing techniques to multiphase flows is not trivial. When employing direct forcing schemes, the treatment of the level-set function near an immersed boundary is challenging and may result in non-physical mass gain or loss near the interface. In addition, most existing methods adopt a static contact line treatment, which is not suitable for many practical applications. In the present work, we propose a numerical formulation, which uses a moving least squared based forcing for the physical variables and a ghost-cell approach for the level-set function to satisfy a dynamic contact angle boundary condition at the immersed boundary. The method is well suited to model multiphase flow around moving immersed boundaries. A hydrodynamic stress model is also implemented to accurately compute the forces on the body from both the liquid and gas phases. We will establish that the proposed formulation does not introduce mass errors. Comparison with experimental and reference numerical simulations for falling droplets and entry-body problems will demonstrate accuracy and robustness.

8:39AM C16.00004 An immersed boundary method with mesh refinement for turbulent flow simulations. SHAO-CHING HUANG, UCLA — The immersed boundary method has been one of the preferred approaches for direct numerical simulation of turbulence that involves irregular or moving boundaries in the computational domain. The method not only bypasses curvilinear or body-fitted mesh generation but also enables the possibility of using fast solvers in the solution procedure, such as FFT-based methods for Poisson equation, making the method highly efficient. However, the convenience of immersed boundary method can be plagued by lack of resolution in the regions where truncation error is large due to the nature of the underlying structured mesh; increasing the local resolution to resolve sharp gradients usually results in rapid growth of the required total computational resources. To address this problem, we develop continuous forcing of the immersed boundary (IB) method, so that the filter Navier-Stokes equations can be solved on a regular Cartesian grid. Wall shear on the boundary is obtained by solving thin boundary layer equation on an embedded mesh. Subgrid viscosity near the wall is modified to maintain the viscosity flux at the face adjacent to the wall equal to the modeled wall shear stress. Non-physical correlation caused by IB force oscillation is eliminated by applying viscosity buffer under the wall. This method has been validated by simulating turbulent channel and pipe flows at high Reynolds numbers, up to \( Re =10^5 \). Furthermore, flows past a circular cylinder at \( Re =10^4 \) and \( 1.4 \times 10^4 \) have also been simulated. The numerical results are shown to be in good agreements with previous numerical and experiment data.

8:52AM C16.00005 An improved wall model based on immersed boundary method for large eddy simulation of turbulent flow over complex/moving boundaries. MING MA, WEI-XI HUANG, CHUN-XIAO XU, Tsinghua University — A hybrid immersed boundary/wall-model based large eddy simulation method is developed to simulate high Reynolds number turbulent flow with complex/moving boundaries. The no-slip boundary condition is imposed by continuous forcing of the immersed boundary (IB) method, so that the filter Navier-Stokes equations can be solved on a regular Cartesian grid. Wall shear on the boundary is obtained by solving thin boundary layer equation on an embedded mesh. Subgrid viscosity near the wall is modified to maintain the viscosity flux at the face adjacent to the wall equal to the modeled wall shear stress. Non-physical correlation caused by IB force oscillation is eliminated by applying viscosity buffer under the wall. This method has been validated by simulating turbulent channel and pipe flows at high Reynolds numbers, up to \( Re =10^5 \). Furthermore, flows past a circular cylinder at \( Re =10^4 \) and \( 1.4 \times 10^4 \) have also been simulated. The numerical results are shown to be in good agreements with previous numerical and experiment data.

9:05AM C16.00006 A Direct Forcing Immersed Boundary Method for Simulations of Heat and Mass Transport with Neumann Boundary Conditions. JACOB JOHNSTON, JINCHENG LOU, NILS TILTON, Colorado School of Mines — The application of Dirichlet boundary conditions with direct-forcing immersed boundaries is well understood. There is less published work, however, on the application of Neumann conditions, particularly to second-order spatial accuracy in the context of finite volume and projection methods. This issue is important for the simulation of membrane filtration systems in which coupled heat and solute transport occur in the presence of complicated surfaces. Though linear interpolation of the forcing over the grid is sufficient to ensure second-order accuracy of Dirichlet conditions, we find that third-order interpolation is required for the implementation Neumann conditions to second-order accuracy. For semi-implicit simulations, this increases the local stencil such that matrices are no longer banded. We use the method to develop a 2D unsteady finite volume code that simulates heat, mass and momentum transport with the projection method of Choi and Moin (Journal of Computational Physics, 1994). We perform numerical experiments to confirm second-order spatial and temporal accuracy, and then use the method to simulate transport in a membrane filtration system.
9:18 AM C16.00007 A Parallel Dynamic Overset Grid Framework for Incompressible Flow Simulations\footnote{This work is supported by the American Heart Association Grant 13SDG17220022, and the computational resources were partly provided by Texas A&M high performance research computing center (HPRC).}, MOHAMMADALI HEDAYAT, IMAN BORAZJANI, Texas A&M University — The overset grid technique enables the flow solvers to handle unsteady moving grid simulations. However, the task of overset grid assembly in parallel for partitioned grid remains challenging. In this study, a new efficient parallel grid assembly and interpolation framework is developed to perform overset grid assembly for structured meshes in a distributed computing environment. This framework is integrated with a sharp interface curvilinear immersed boundary (CURVIB) flow solver to handle multiple overlapping flow domains. To achieve a good parallel performance several steps are implemented in our framework: 1) using oriented bounding boxes (OBB) instead of axis-aligned bounding boxes; 2) using a walking strategy for donor search; 3) directly integrating grid assembly to the flow solver; 4) efficient vectorized implementation for velocity interpolation; and 5) using a general non-inertial frame of reference flow solver to prevent the recomputation of curvilinear grid. The framework verified and validated against experimental and numerical benchmarks. Our results show a good scalability and accuracy for this new framework. In addition, its capabilities are demonstrated by simulating a school of aquatic swimmers in a diamond shape.

9:31 AM C16.00008 High-Order Ghost-Point Method for Non-Conforming Boundaries\footnote{Laboratory Directed Research and Development (LDRD), Los Alamos National Laboratory}, PRakash Shrestha, Peter Brady, Vitaliy Gryya, Daniel Livescu, Los Alamos National Laboratory — We investigate numerical properties of constrained moving least squares method for numerical implementation of solid boundary conditions (CMLS, an immersed boundary method) by Qu, Shi and Batra (2018) coupled with central finite differences for interior derivatives. This study represents an extension of the original method, which uses first order interpolation / extrapolation for the ghost and image points, as well as dissipative interior discretization. The objectives of the investigation are to determine the suitability of the method for direct numerical simulations of turbulent flows in complex geometries and to find an optimal set of built-in parameters in terms of achieving high order of accuracy and stability of the method for a wide range of canonical test problems. The test problems include a 1-D linear scalar wave equation, for which rigorous stability and conservation properties can be discussed, and 2-D nonlinear tests using Burgers’ equation and the compressible Euler equations with manufactured solutions. Preliminary data indicate that the method can achieve good stability and accuracy properties.

9:44 AM C16.00009 A single-sided direct-forcing diffused immersed boundary method for correct local velocity gradient computation, CHENG PENG, Pennsylvania State University, LIAN-PING WANG, Southern U of Sci and Tech and U of Delaware — Current algorithms of the immersed boundary method (IBM) based on diffused interfaces are not able to correctly calculate the velocity gradients within the diffused solid-fluid interfaces. This is because the non-zero boundary forcing creates a difference in the actual momentum equation solved in IBM from the physical one described by the Navier-Stokes equations with a sharp fluid-solid no-slip interface. A single-sided direct-forcing IBM algorithm is proposed to remove the boundary forcing from the fluid region. The capability of the proposed algorithm in correctly computing velocity gradients within all fluid region is validated in both laminar and turbulent flows. A technique to speed up the convergence of no-slip enforcement via force iteration is also introduced. This technique works for the proposed algorithm and other IBM algorithms.

9:57 AM C16.00010 An Immersed Boundary Method Coupled with a Level Set and Dynamic Overlapping Grids Approaches for Free Surface and Moving Bodies Problems\footnote{Membership Pending}, Riccardo Broglia\footnote{1}, Antonio Posa, Danilo Durante, CNr-lnm — An immersed-boundary (IB) approach was developed within an existing level-set/dynamic overlapping-grids finite-volume solver. An IB strategy is utilized together with curvilinear grids capabilities, keeping cells count under control, a main disadvantage for the classical IB methods using Cartesian grids. Moreover, the IB is identified by an additional level-set function, i.e., a distance function defined at each node of the computational grid, whose zero level represents the fluid/solid interface. One of the main advantages of the proposed approach is the coupling with a dynamic overlapping-grids methodology and a single-phase level-set approach. The former is especially convenient in presence of moving bodies: updating the position of the Lagrangian grid, which discretizes the surface of the body, relative to the Eulerian grid, is not required, since the Eulerian grid attached to a moving IB can follow the body during its motion. The latter is efficiently adopted to handle the presence of an air/water interface. Here the methodology is discussed in detail. Test cases feature stationary and moving bodies as well as complex geometries and free-surface flows. Results from present IB computations are compared with body-fitted solutions and data from literature.

Sunday, November 24, 2019 8:00AM - 10:10AM – Session C17 Focus Session: Recent Advances in Data-driven and Machine Learning Methods for Turbulent Flows I 4c4 - Karthik Duraisamy, University of Michigan

8:00 AM C17.00001 Unsteady Flow Field Predictions Using Multi-level Deep Convolutional Autoencoder Networks\footnote{The authors acknowledge support from the Air Force under the Center of Excellence grant FA9550-17-1-0195, titled “Multi-Fidelity Modeling of Rocket Combustor Dynamics.”}, Jiayang Xu, Karthik Duraisamy, University of Michigan — A machine learning framework is proposed for unsteady flow field predictions. Three levels of deep neural networks are used, with the goal of predicting the future state of the flow for unseen global parameters. A Convolutional autoencoder is used as the top level to encode the high-dimensional data sequence along spatial dimensions into a sequence of latent variables. A temporal convolutional autoencoder serves as the second level, which further encodes the output sequence from the first level along the temporal dimension, and outputs a set of latent variables that fully captures the spatio-temporal evolution of the flow field. A fully connected network is used as the third level to learn the mapping between these latent variables and the global parameters from training data, and predict them for new parameters. For future state predictions, the second level uses temporal convolutional network to predict subsequent steps of the output sequence from the top level. Outputs at the bottom level are decoded to obtain the high-dimensional flow field sequence at unseen global parameters and/or future states.
8:13AM C17.00002 Physics-Constrained Convolutional LSTM Neural Networks for Generative Modeling of Turbulence

ALANSE MOHAN, DANIEL LIVESCU, Los Alamos National Laboratory, MICHAEL CHERTKOV, University of Arizona — High fidelity modeling of turbulence and related physical phenomena is often challenging due to its prohibitive computational costs or the lack of accurate theoretical models. In the recent years, deep learning approaches have shown much promise in modeling of complex systems. A major challenge in deep learning for generative modeling of turbulence is the chaotic, high dimensional and spatio-temporal nature of the data, which makes the learning process ineffective and/or expensive. Previous work by the authors (Mohan et al., 2018) showed the capability of Convolutional LSTM (ConvLSTM) neural networks in modeling high fidelity 3D turbulence. ConvLSTM augments the traditional architecture of an LSTM cell with a convolutional layer to learn spatial features in high dimensional datasets. In this work, we introduce various physical constraints of incompressible turbulent flows into ConvLSTM networks. We demonstrate its efficacy by learning and predicting physically consistent dynamics of a homogeneous isotropic turbulence DNS dataset. Statistical tests are also performed on the predicted turbulence to assess the quality of the physical constraints on the "learned" physics. Finally, we discuss challenges and opportunities with ConvLSTM when enforced with physical constraints, with additional focus on computational scaling of this approach to large datasets.

LANL/DOE LDRD

8:26AM C17.00003 Physics Informed Learning of Lagrangian Turbulence: Velocity Gradient Tensor over Inertial-Radius Geometry

YIFENG TIAN, DANIEL LIVESCU, University of Arizona — The phenomenological model of coarse-grained velocity gradient tensor (VGT) constructed by considering the Lagrangian dynamics of four points, or the tetrad, is extended under the Physics-Informed Machine Learning (PIML) framework. The pressure hessian contribution is re-constructed from the dynamics of Lagrangian tetrad, which provides an improved representation of its magnitude and orientation. The unclosed incoherent small scale fluctuations are modeled using ML techniques trained on Langrangian data from a high-Reynolds number Direct Numerical Simulation (DNS). Certain constraints, such as Galilean invariance, rotational invariance, and zero-pressure work condition, are enforced to implement known physics into the ML model. Then, a comprehensive diagnostic test is performed. Statistics of the flow, as indicated by the joint PDF of second and third invariants of the VGT at different coarse-grained scales, show good agreement with the ground-truth DNS. Some important features regarding the structure of the turbulence are correctly reproduced by the model including skewed distribution of the velocity gradient, vorticity-strain rate alignment and vortex stretching mechanism. The pressure hessian and small-scale contributions to Lagrangian dynamics are also well-captured.

8:39AM C17.00004 Prediction of Aerodynamic Flow Fields Using Spectral Convolutions on Graph Networks

JAMES DUVALL, KARTHIK DURAIKUMAR, YASER AFSHAR, University of Michigan — In this work, spectral methods for performing localized convolutions on graphs are investigated to predict aerodynamic flow fields given the geometry of the surface, and flow configurations therein. Previous work has shown that convolutional neural networks (CNNs) can be used for this purpose. CNNs, however, are restricted to Euclidean domains, and their use requires interpolation from non-regular mesh representations typical of flow solutions on an evenly spaced Cartesian mesh. This represents a loss of information as flow solvers include a clustering of points near boundary layers and other regions of sharp gradients. We pursue graph convolutional networks (GCNs) which operate over non-Euclidean data represented by a graph. GCNs generalize many of the characteristics associated with CNNs. Localized filtering operations are defined in the graph spectral domain, and depend on the graph Laplacian, which is graph structure dependent. Although meshes for different geometries may be spatially distinct, they share spectral characteristics if a binary adjacency matrix is considered. GCNs operating directly on graph representations of spatial flow solver meshes are shown to predict aerodynamic flow fields on unseen airfoil shapes and operating conditions to a good degree of accuracy.

8:52AM C17.00005 Potential of using deep neural networks for turbulent-flow predictions

RICARDO VINUESA, PREM A. SRINIVASAN, LUCA GUASTONI, HOSSEIN AZIZPOUR, PHILIPP SCHLATTER, KTH Royal Institute of Technology — The capabilities of deep neural networks to predict temporally evolving turbulent flows are evaluated in this work. To this end, we employ the nine-equation shear flow model by Moehlis et al. (New J. Phys. 6, 56, 2004) as a low-order dynamical representation of near-wall turbulence. We thoroughly tested two different neural networks: the multilayer perceptron (MLP) and the long short-term memory (LSTM) network, and determined the best configurations for flow prediction (i.e., number of layers, number of units per layer, dimension of the input, weight initialization strategy and activation function). Because of its ability to exploit the sequential nature of the data, the LSTM network outperformed the MLP. In particular, relative errors of 0.45% and 2.49% were obtained in mean and fluctuating quantities respectively with the LSTM. Furthermore, this network also led to an excellent representation of the dynamical behavior of the system, characterized by Poincaré maps and Lyapunov exponents. The present results underpin future applications aimed at developing inflow and off-wall boundary conditions for turbulence simulations, and data-driven flow reconstruction of more complex wall-bounded turbulent flows, including channels and developing boundary layers.

9:05AM C17.00006 Turbulence inflow generation using generative adversarial network

JUNHYUK KIM, CHANGMOO LEE, Yonsei University — Using unsupervised learning, we developed an inflow generator that performs better than previous synthetic methods. Direct numerical simulations of turbulent channel flow were carried out at three Reynolds numbers, and then temporally successive flow fields in a cross-sectional (y-z) plane were collected. Using the collected data, we trained a novel model, RNN-GAN, which is composed of a recurrent neural network (RNN) and a generative adversarial network (GAN). Here, RNN represents time-variation of generated flow, while GAN represents a spatial correlation of the flow. Our trained RNN-GAN produces surprising results. First, the generated flow is qualitatively and statistically accurate as compared with DNS. Second, it is possible to generate the flow not only at the trained Reynolds numbers but also at the other Reynolds numbers, although the extrapolated case shows a little deterioration of statistical accuracy. The generated flow is stochastically varying over time, unlike a supervised learning method. Finally, the domain size of the generated flow is extendable. These results indicate that our model provides good inflow generator required for developing channel flow.
9:18AM C17.00007 Physics-informed Spatio-temporal Deep Learning Models, KARTHIK KASHINATH, ADRIAN ALBERT, RUI WANG, MUSTAFA MUSTAFA, Lawrence Berkeley Lab, ROSE YU, Northeastern University — Simulating the spatio-temporal evolution of a complex system over a realistic domain is extremely compute-intensive with current PDE-solvers. Deep learning (DL) shows great promise for augmenting or replacing compute-intensive parts of computational physics models. However, it remains a grand challenge to incorporate physical principles in a systematic manner to the design, training and inference of such models. Physics informed DL aims at defining parameterizations of physical systems into DL models, but existing studies are either limited to purely linear dynamics or purely spatial constraints of physical systems. We study spatiotemporal modeling of velocity fields for a highly nonlinear turbulent flow using various state-of-the-art physics informed DL methods. We benchmark these methods on the task of forecasting velocity fields at different future time horizons, given historic data of different lengths. We find that incorporating prior physics knowledge can not only speed up the training process but improve model performance. Our results show that the Spatiotemporal Generative Networks with an autoregressive U-net as the generator performs the best for varying forecasting horizons.

9:31AM C17.00008 Neural Network Optimization Under Partial Differential Equation Constraints, KARTHIK KASHINATH, Lawrence Berkeley Lab, CHIYU JIANG, U C Berkeley, GAVIN ELI JERGENSEN, MR PRABHAT, Lawrence Berkeley Lab, PHILIP MARCUS, U C Berkeley, PHYSICS-INFORMED DEEP LEARNING COLLABORATION — Enforcing physical constraints to solutions generated by neural networks (NN) remains a challenge, yet it is essential to their accuracy and trustworthiness. We propose a novel differentiable spectral projection layer that efficiently enforces spatial PDE constraints using spectral methods, yet is fully differentiable, facilitating end-to-end training. We train a 3D Conditional Generative Adversarial Network for turbulence superresolution, whilst guaranteeing the spatial constraint of zero divergence. Results show that the model produces realistic flow fields with more accurate flow statistics when trained with hard constraints, compared to soft constrained and unconstrained baselines. We also present a method of applying multiple PDE constraints by modifying the loss function directly. We provide theoretical guarantees of convergence and evaluate the computational complexity of the method. We offer an approximation which trades convergence guarantees for improved speed. Experimentally, we train constrained NN to learn continuous representations of solutions to the linear Helmholtz equation and the nonlinear steady-state Navier-Stokes equation. We show that the model outputs better respect the underlying physics, but note the complexity restricts its application to small NN.

9:44AM C17.00009 Data-driven prediction of a multi-scale Lorenz 96 chaotic system using a hierarchy of deep learning methods: Reservoir computing, ANN, and RNN-LSTM, PEDRAM HASSANZADEH, ASHEESH CHATTOPADHYAY, KRISHNA PALEM, DEVIKA SUBRAMANIAN, Rice University — The performance of three deep learning methods for predicting short-term evolution and reproducing the long-term statistics of a multi-scale spatio-temporal Lorenz 96 system is examined. The methods are: echo state network (a type of reservoir computing, RC-ESN), deep feed-forward artificial neural network (ANN), and recurrent neural network with long short-term memory (RNN-LSTM). This Lorenz system has three tiers of nonlinearly interacting variables representing slow/large-scale (X), intermediate (Y), and fast/small-scale (Z) processes. For training or testing, only X is available; Y and Z are never known/used. It is shown that RC-ESN substantially outperforms ANN and RNN-LSTM for short-term prediction, e.g., accurately forecasting the chaotic trajectories for hundreds of numerical solver’s time steps, equivalent to several Lyapunov timescales. RNN-LSTM and ANN show some prediction skills as well; RNN-LSTM bests ANN. Furthermore, even after losing the trajectory, data predicted by RC-ESN and RNN-LSTM have probability density functions (PDFs) that closely match the true PDF, even at the tails. PDF of the ANN data deviates from the true PDF. Implications, caveats, and applications to data-driven surrogate modeling of complex dynamical systems are discussed.

9:57AM C17.00010 Data-driven super-parametrization using deep learning for large scale turbulent flow in weather/climate modeling, ASHEESH CHATTOPADHYAY, ADAM SUBEL, PEDRAM HASSANZADEH, KRISHNA PALEM, Rice University — Some of the physical processes that play key roles in turbulent systems such as weather/climate systems occur at such small spatial and fast time scales that trying to explicitly solve for them can lead to computationally intractable numerical models. These subgrid-scale processes (denoted by variable Y hereafter), are often parameterized using semi-empirical/physics-based schemes as a function of the large-scale/slow variables (X) that are explicitly solved. Multi-scale numerical models that explicitly solve for X and Y, but at different numerical resolutions, dubbed super-parameterization (SP), has been shown to improve simulations of large-scale turbulence in climate models, but at a large computational cost. More recently, several studies have shown promises of using deep neural networks, trained on data from high resolution climate models, for data-driven parameterization (DDP) of Y as a function of X. Here, we show that Gated Recurrent Units (GRU) can be used for data-driven super-parameterization (DDSP): To solve for X numerically at low resolution and emulate the evolution of Y with a GRU at higher numerical resolutions, at a much lower computational cost, and similar accuracy as that of SP on a multi-scale Lorenz 96 test bed.

Sunday, November 24, 2019 8:00AM - 10:10AM — Session C18 Focus Session: Competing Roles of Surfactants in Free Surface Flows with Hydrodynamic Singularities 400 - Pritish Kamat

8:00AM C18.00001 The Surprising Influence of Marangoni Stress on Near-Singular Dynamics in Breaking Surfactant-covered Liquid Threads, PRITISH KAMAT, Dow Incorporated., OS-MAN BASARAN, Purdue University — The singularity arising during thread breakup is a precursor to drop formation and is accompanied by flows directed away from the breakup location that grow stronger as pinch-off nears. When surfactants are present at interfaces, these outward flows convect surfactants away from the singularity such that the dynamics proceeds in local absence of surfactants. Despite this, it has been observed that even small amounts of surfactants can have a substantive effect on breakup. Experiments show reduced rates of thinning, altered satellite sizes, and formation of fractal structures—microthread cascades—whereas simulations show that thinning filaments can recover and escape pinch-off in the presence of surfactants. Here, we show that evacuation of surfactants from the breakup singularity indirectly leads to the generation of large concentration (surface tension) gradients in the vicinity of but not at the breakup location. The resultant gradients generate Marangoni stresses that are large enough to compete with other forces, and are key to how surfactants influence near-singular dynamics. Here, we use simulations to shed light on two distinct contexts where the competition between Marangoni stresses and other forces perceptibly influences the fate of the breakup singularity.
8:13AM C18.00002 Influence of the surface viscosities on the pinching of a pendant droplet loaded with SDS\textsuperscript{1} , MIGUEL A. HERRADA, Universidad de Sevilla, ETSI, 41092 Sevilla, Spain, ALBERTO PONCE-TORRES, MANUEL RUBIO, JOSE M. MONTANERO, Depto. de Ingeniería Mecánica, Energética y de los Materiales, Universidad de Extremadura, E-06006 Badajoz — The interfacial viscosities of relatively viscous insoluble surfactants are known to affect the dynamics of a liquid thread close to the free surface pinching [1]. Here, we analyze both numerically and experimentally the breakup of a pendant water drop loaded with SDS. We focus on the influence of the monolayer of SDS on the free surface minimum radius \( R \). The results show remarkable agreement between the experiments and numerical simulations for the pure DIW case. When a surfactant is introduced, it creates a monolayer that alters the pinch-off dynamics. If only solute-capillarity and Marangoni convection are considered in the numerical simulations, there is a measurable deviation with respect to the experimental results for \( R_{\text{min}}(\tau) < 5 \) \( \mu \text{m} \). We considered the surface shear and dilatational viscosities in the simulation to reproduce the entire range of experimental data. The value of the shear viscosity is consistent with the upper bound reported in the literature [1]. [1] A. Ponce-Torres, J. M. Montanero, M. A. Herrada, E. J. Vega, and J. M. Vega, Phys. Rev. Lett. 118, 024501 (2017).

8:26AM C18.00003 The role of surface viscous stresses in the liquid thread breakup, HANSOL WEE, Purdue University, PRITISH KAMAT, Dow Incorporated, OSMAN BASARAN, Purdue University — Many industrial processes involving emulsions, foams, and inkjet printing exploit the ability of surfactants to adsorb onto and lower the surface tension of water-air and water-oil interfaces. In addition to lowering surface tension, surfactants may induce Marangoni stresses and cause surface rheological effects. Therefore, the dynamics of free surface flows can be significantly altered by their presence. Although much attention has been paid to date to the influence of Marangoni stresses and solutocapillarity, the effect of surface viscous stresses has been inadequately studied given the difficulty in measuring surface viscosities due to the presence of surfactants. Using a simple model that they vary linearly with concentration, we examine their effect on thread breakup by 1D simulations using the slender-jet approximation. The results obtained with the 1D algorithm are confirmed by direct comparison against predictions made with a 3D but axisymmetric free surface solver.

8:39AM C18.00004 How surfactants influence the drop size in sprays , DANIEL BONN, Institute of Physics, University of Amsterdam — Spraying is a widely used method to produce a liquid sheet that break up into droplets of a certain size distribution. When spraying simple liquids, it is known which experimental parameters determine the droplet size distribution. For many applications however, surfactants are added, producing a hitherto unknown effect on the droplet size distribution. Using two generic types of spraying nozzles, we sprayed solutions of different types of aqueous surfactants and measured the droplet size distribution of the sprays. We find that the breakup of surfactant solutions is similar to that of pure water but results in droplets that are on average smaller. The resulting droplet size distribution can be well described using the predictions for simple liquids provided that we replace the parameter of the equilibrium surface tension with the dynamic surface tension of the surfactant solution at a surface age of 20 ms, which is the characteristic time for destabilization and breakup of a liquid sheet. By rescaling them with the mean droplet size, the droplet size distributions of water and sprays with different concentrations of surfactants all collapse onto a single curve and can be well described using the compound Gamma function found previously for pure liquids.

8:52AM C18.00005 Restoring universality to the pinch-off of a bubble , AMIR PAHLAVAN, HOWARD STONE, Princeton University, GARETH MCKINLEY, RUBEN JUANES, MIT — We observe the formation of bubbles and drops on a daily basis, from dripping faucets to raindrops entraining bubbles on the surface of a lake. The pinch-off of a bubble is an example of the formation of a singularity, exhibiting a characteristic separation of length and time scales. Because of this scale separation, one expects universal dynamics that collapse into self-similar behavior determined by the relative importance of viscous, inertial, and capillary forces. Here, we report on the intriguing observation that confinement makes the pinch-off of a bubble a universal process, as opposed to the unconfined case, where pinch-off is sensitive to the details of the experimental setting. We show that the pinch-off dynamics of a bubble confined in a capillary to a sequence of two distinct self-similar regimes controlled by a balance between viscous and capillary forces. We demonstrate that the early-time self-similar regime restores universality to bubble pinch-off by erasing the system’s memory of the initial conditions. Our observations have implications for immiscible flow phenomena from microfluidics to geophysical flows, where confinement, together with fluid-solid physicochemical interactions, play a key role.

9:05AM C18.00006 Flow statistics of Marangoni contracted sessile drops , STEFAN KARPITSCHKA, OLINKA RAMIREZ, Max Planck Institute for Dynamics and Self Organization, Göttingen, Germany, MICHEL A. HACK, Physics of Fluids Group, University of Twente, Enschede, The Netherlands, WOJCIECH KWIECINSKI, E. STEFAN KOOLJ, Physics of Interfaces Group, University of Twente, Enschede, The Netherlands — A droplet of two miscible liquids should spread over a high-energy surface until complete wetting. However, if one component is more volatile and has a higher surface tension, a quasi-stationary non-vanishing apparent contact angle can be observed. This is caused by the enrichment of the residual component near the contact line and the associated surface tension gradient. A hydrodynamic-evaporative model, using a long-wave approximation for the droplet coupled to diffusion limited evaporation predicts a balance between Marangoni and capillary flows and a power law between the apparent contact angle and the ambient humidity [Karpitschka et al., Langmuir (2017)]. This explanation differs from a recent model, where the low surface tension of a precursor around the droplet is held responsible [Benesiglio et al., Soft Matter (2018)]. A discrimination between possible mechanisms requires experimental resolution of the flow in the drop. We present uPIV measurements and relate them to the apparent shape of the drop, for aqueous solutions of various short chain carbon diols. Depending on the surface activity of the diol, its concentration, and the ambient humidity, we observe different regimes, indicating that multiple mechanisms lead to the observed angles.

9:18AM C18.00007 Marangoni effects enabling interfacial singularities and topological changes in fluid flows , ROUSLAN KRECHETNIKOV, University of Alberta — In this talk I will address two geometric effects of surface tension gradients: formation of interfacial singularities and change in the flow topology compared to the clean interface case. In the first part, I will focus on a necessary condition for the existence of geometric singularities – divergence of curvature at fluid interfaces – in the solutions of fluid dynamic equations. Besides establishing a relation to dynamic singularities – unboundedness of the velocity field – explicit asymptotic solutions of the Navier-Stokes equations are developed as well. Next, using as an example the phenomena of tip-streaming, with the help of asymptotic matching we resolve the associated Marangoni-driven singularities providing explicit asymptotic formulas for the scaling of the emitted droplets. In the second part, using the Landau-Levich problem of dip coating as a paradigm, we demonstrate how Marangoni stresses are capable of changing the flow topology by moving the stagnation point initially residing at the interface in absence of surfactants into the bulk once surfactants are added to the system. This finding not only explains thickening of the deposited film as induced by Marangoni effects, but also illustrates another geometric effect surface tension gradients may cause.
9:31AM C18.00008 Coalescence of surfactant-laden drops in liquid-liquid emulsions
VISHRUT GARG, Air Products and Chemicals, Inc., OSMAN BASARAN, Purdue University — Determining the timescale over which liquid-liquid emulsions separate into their constituents is crucial for many processes, e.g. separating crude oil from brine. This timescale depends on the dynamics of collision and coalescence of liquid drops immersed in a second liquid which can be significantly altered by the presence of surfactants at the liquid-liquid interface. We simulate the approach, collision, and eventual coalescence of two drops immersed in an ambient liquid in the presence of insoluble surfactants where both liquids are incompressible Newtonian fluids. The governing equations are augmented to account for long range van der Waals interactions that become significant as the separation between the drops falls below a few hundred nanometers and solved using a Galerkin finite element based algorithm. In contrast to drops with clean interfaces which coalesce during their first approach, surfactant laden drops are seen to rebound on first approach before coalescing on their subsequent approach. This rebound results in increased drainage times. We examine the physics underlying drop rebound in the presence of surfactants.

9:44AM C18.00009 Coating and Crumpling of Particle-Coated Bubbles in Confined Geometries
SHELLEY ANNA, CHARLES SHARKEY, ZIXIAN CUI, Carnegie Mellon University — We examine bubble flow in a capillary filled with a suspension of surface-active particles. Silica nanoparticles are rendered surface active when mixed with cationic CTAB surfactant, which adsorbs to the silica surface in a glycerol-water mixture. Bubbles are dispersed via a co-flow nozzle at varying bubble lengths and capillary numbers. Fluid film thickness is measured along the length of the bubble. The measurements are compared with bubble flow through surfactant solutions and with predictions from a Bretherton-type model. The adsorbed particle-surfactant complexes form an evolving rigid layer at the trailing end of the bubble. Two critical bubble lengths are observed. Above the first critical length, the bubble contains two distinct film thicknesses. The thickened film at the trailing end arises from the rigid particle layer on the interface. Above the second critical length, the trailing bubble cap crumples and collapses. Crumpling occurs soon after the bubble is dispersed into the capillary, and the critical length varies with bubble velocity. These results allow us to infer rheological and mechanical properties for the interface that are associated with the crumpling phenomenon.

9:57AM C18.00010 Waves on an interface with surfactant
WILLEM VAN DE WATER, Laboratory for Aero and Hydrodynamics, Delft University of Technology, YUKMAN LAU, JERRY WESTERWEEL, Laboratory for Aero and Hydrodynamics Delft University of Technology, DAMIR JURIC, JALEL CHERGUI, Laboratoire d'informatique pour la Mécanique et les Sciences de l'Ingénieur (LIMSI), Centre National de la Recherche Scientifique (CNRS), SEUNGWON SHIN, Department of Mechanical and System Design Engineering, Hongik University, Korea — The presence of surfactant on an interface between two immiscible fluids can dramatically change the interfacial tension. The question is whether this is still so when the interface is rippled through waves which redistribute surfactants. We study Faraday waves on an oil-water interface and use benchmark surfactants with increasing concentration that reaches into the realm of ultralow interfacial tension ($\sigma = O(10^{-10}) \text{N/m}$). In the experiments we measure the wavelength, wave height and threshold acceleration amplitude and compare them to a Floquet analysis. Surprisingly, the dispersion of capillary waves (frequency 20 Hz) points to a much stiffer interface at surfactant concentrations where it should be ultralow. We hypothesize the key role of surfactant dynamics. This is supported by numerical simulations of Faraday waves in the presence of surfactant gradients.

Session C19 CFD: High-order and Shock-capturing Methods
401 - Bryce Campbell, Lawrence Livermore National Laboratory

8:00AM C19.00001 High-order energy-stable boundary treatment for finite-difference cut-cell method
NEK SHARAN, PETER BRADY, DANIEL LIVESCU, Los Alamos National Lab — Cut-cell methods simplify grid generation for fluid-flow simulations over complex geometries. Construction of high-order boundary implementation for cut-cell discretization that also provably satisfies stability and conservation constraints, however, remains a challenge, especially for hyperbolic equations. Existing energy-stability proofs of finite-difference methods for initial-boundary value problems require imposing the boundary conditions weakly or by a projection approach, where the computed boundary values may not be exact. Inexact boundary values may be adequate for estimates in certain applications, but they can adversely influence turbulence/mixing statistics in a direct numerical simulation. A framework to prove energy-stability with strong boundary treatment is developed and used to obtain boundary implementation for a Cartesian cut-cell discretization. Linear and non-linear numerical tests to verify the accuracy, stability and conservation properties of the developed method will be discussed.

8:13AM C19.00002 ABSTRACT WITHDRAWN

8:26AM C19.00003 Multidimensional optimization of non-linear shock capturing schemes
RAYNOLD TAN YIYUN, ANDREW OOI, RICHARD SANDBERG, University of Melbourne — In this work, a quasi-linear semi-discrete analysis of shock capturing schemes in multi-dimensional wavenumber space is proposed. Using the dispersion relation of the two dimensional convection and linearized Euler equations, the spectral properties of a spatial scheme can be quantified in two dimensional wavenumber space. A hybrid scheme which combines the merits of the Minimum Dispersion and Controllable Dissipation (MDCD) scheme with the Targeted Essentially Non-Oscillatory (TENO) scheme was developed. Using the proposed analysis framework, the hybrid scheme was spectrally optimized in multidimensional wavenumber space such that the linear part of the scheme can be separately optimized for its dispersion and dissipation properties. In order to demonstrate the improved spectral properties of the new scheme, a series of one dimensional and multidimensional numerical tests were conducted.
8:52AM C19.00005 High-order simulation of flow around geometries on octree meshes using Brinkmann penalization. SABINE ROLLER, HARALD KLIMACH, NIKHIL ANAND, NEDA EBRAHIMI POUR, University of Siegen — Simulation of flow and acoustics over large domains and long distances require highly efficient CFD methods as well as highly scalable implementations on modern supercomputers. High-order Discontinuous Galerkin (DG) implemented on octree meshes fulfill these requirements. Unfortunately, the representation of obstacles in the domain — which usually cause the generation of acoustics — is an issue for high-order methods. In combination with the high order DG (orders up to 32 or 64, i.e. ≈2) the representation of the obstacle surface needs to hold an approximation order equivalent to the scheme order, otherwise the scheme loses its best property at exactly that point. This contribution will investigate the implementation of geometry representations with high-order on a given Cartesian mesh by using a Brinkmann penalization strategy.

9:05AM C19.00006 A numerical strategy for efficient multi-scale and multi-physics simulations using partitioned coupling. NEDA EBRAHIMI POUR, SABINE ROLLER, University of Siegen, Germany — The simulation of complex problems such as multi-scale and multi-physics is still challenging when considering the computational efficiency of those simulations. Simulating all these effects in a single domain is not feasible monolithically, since different scales appear in different areas of the domain, which have to be resolved properly. In order to simulate these kinds of problems in a more efficient way, we make use of partitioned coupling, where we split the domain into subdomains where each of them uses the appropriate set of equations, scheme order and mesh resolution. The subdomains are weakly connected to each other at the boundaries. For the communication and data-exchange between them a coupling approach integrated in our simulation framework APES is used. We will present first results of the coupled scenario and show how well we can reduce the computational cost, when compared to the monolith simulation by means of a small test case, which is still feasible monolithically.

9:18AM C19.00007 A second-order method for convection-diffusion equation across interfaces separated by boundaries of flow. XIANGLONG WANG, University of Michigan and Tulane University, MARK MEYERHOFF, University of Michigan, JOSEPH BULL, Tulane University — Biological mass transport often involves transport across interfaces separated by presence of flow. An example is the recent development of nitric oxide releasing catheters that release nitric oxide into the bloodstream to prevent biofilm formation. The presence of flow often creates large gradients in mass concentration with sharp contrast in Peclet numbers across the interface. Solving such problems with computational methods are challenging, since proper shock capturing methods are essential to resolve these shocks. Our goal is to accurately resolve the shocks present in convection-diffusion problems separated by boundaries of flow. To achieve this goal, we developed a 3D Cartesian-coordinates based method on a model problem simulating release of substance-doped catheters into the bloodstream on a non-orthogonal hexagonal grid. We applied proper directional slope limiting for calculating convection flux and multi-point flux approximation (MPFA) L-method for calculating diffusion flux. This method allows us to achieve stable solutions of the convection-diffusion equation in our model problem with near second-order accuracy for local Peclet numbers up to 5.0. The ability of perform such simulation is essential for guiding the development of nitric oxide releasing catheters.

9:31AM C19.00008 Data-driven optimization strategies for staggered-grid Lagrangian methods. JASON ALBRIGHT, MIKHAIL SHASHKOV, NATHAN URBAN, Los Alamos National Laboratory — For applications dealing with shock waves, algorithmic ingredients like artificial viscosity are essential to avoid highly oscillatory solutions. Yet they also introduce additional model parameters that are usually poorly constrained and consequently are often hand-tuned to problem specific applications. In this talk, we produce optimal values for parameters controlling the amount of artificial viscosity and artificial heat flux through a combination of large ensemble sampling and machine learning-based optimization techniques. We illustrate that the optimal parameter set significantly improves the accuracy, efficiency, and flexibility of the underlying scheme. Although, we illustrate this strategy for a particular discretization scheme, this methodology may be generalized to a much wider variety of existing methods.
9:44AM C19.00009 Reconstructing the piecewise-smooth solution of the Poisson equation for Chebyshev-collocation solution with pointwise exponential convergence. SUDIPTA RAY, SANDEEP SAHA, Department of Aerospace Engineering, Indian Institute of Technology — Computation of an exponentially accurate solution of the Poisson equation which is discontinuous across an interface is restricted by the occurrence of the Gibbs phenomenon. Spectral discretization with inaccurate implementation of the jump conditions produces aphysical oscillations in the numerical solution with algebraic convergence. In the present work, a Chebyshev-collocation spectral discretization is implemented to compute the piecewise-smooth solution of the Laplace and the Poisson equation in two dimensions, where the solution domain contains an interface of complex geometrical shape. The solution is expressed as the sum of a smooth function and a modified Heaviside function at the interface. The unit Heaviside step function is weighted by a smooth jump function which allows the conditions at the interface to be imposed exactly. The modified Heaviside function for interface conditions on the solution and the gradient along the normal is expressed with a weak form expansion. In the presence of global information on the jumps in the form of analytical expressions, the method demonstrates pointwise exponential convergence for the problems considered. In addition, the method appears to be insensitive to perturbations to the interface below the local grid spacing.

9:57AM C19.00010 Reconstructing the piecewise-smooth solution of ordinary differential equations for Chebyshev-collocation solution with pointwise exponential convergence. SUDIPTA RAY, SANDEEP SAHA, SUDIPTA RAY, Department of Aerospace Engineering, Indian Institute of Technology — Physical problems with interfacial discontinuity in the solution or material property are characterized by piecewise-smooth solutions. Numerical computation of problems with interfacial discontinuity requires accurate resolution of the interface conditions. For finite-order methods, the problem may be resolved with local corrections near the interface. Application of spectral methods to approximate the piecewise-smooth solution without an accurate implementation of interface conditions, however, results in the Gibbs oscillations and non-convergent numerical solution. In order to overcome the Gibbs phenomenon, the discontinuous solution is expressed as the sum of a smooth function and a modified Heaviside function at the location of the discontinuity. The unit Heaviside step function is modified with a smooth jump function which exactly satisfies the conditions of discontinuity at the interface. A weak form expansion of the jump function that uses interface conditions up to the first derivative for a second-order ordinary differential equation is proposed. Implementation of a Chebyshev-collocation discretization to problems where the discontinuities in the solution are known in analytic form produces numerical solution that converges exponentially in the maximum norm.

Sunday, November 24, 2019 8:00AM - 10:10AM
Session C20 Geophysical Fluid Dynamics Atmosphere

8:00AM C20.00001 Velocity-defect laws, log law and logarithmic friction law in the convective atmospheric boundary layer\(^1\), MENGJIE DING, CHENNING TONG, Clemson University — The mean velocity profile (MVP) in the convective atmospheric boundary layer (CBL) is derived analytically employing the shear-stress budget equations and the mean momentum equations. The multi-point Monin–Obukhov similarity (MMO) recently proposed provides the scaling properties of the one-point statistics in these equations. Our previous studies have shown that the CBL is mathematically a singular perturbation problem. Thus, we obtain the MVP using the method of matched asymptotic expansions. Three scaling layers are identified: the outer layer, the inner–outer layer and the inner-inner layer. Two new velocity–defect laws are discovered: the mixed-layer velocity–defect law and the surface-layer velocity–defect law. The local-free-convection MVP is obtained by asymptotically matching the expansions in the first two layers. The log law is obtained by matching in the last two layers. The von Karman constant is obtained using velocity and length scales, and therefore has a physical interpretation. A new friction law, the convective logarithmic friction law, is obtained. The present work provides an analytical derivation of the MVP hypothesized in the Monin–Obukhov similarity theory, and is part of a comprehensive derivation of the MMO scaling from first principles.

8:13AM C20.00002 Annual variability of atmospheric surface layer characteristics and wind/temperature patterns in Qatar, REZA SADR, YUAN LI, Texas AM University, College Station — Surface wind patterns influence the anemochory, pollutants dissipation. The research of the characteristics of surface layer and turbulence exchange processes can contribute to the local economic construction and understanding of regional plant ecological environment. This work reports on the weather variation in the coastal region of northern Qatar peninsula in the Persian Gulf. Wind velocity, direction, humidity and temperature data for the coastal site of Qatar are recorded from August 2015 to September 2016. Sonic anemometer and weather station data was collected at 9 m height tower. Seasonal wind patterns are analyzed. Shamal wind from Northwest is prevailing for all the four seasons and the annual wind speed is 4.67 m/s. Temperature in June, July, August and September are the highest, with the lowest air pressure and the most occurrence of the summer Shamal. Two other public data are used for comparison with the present data. The normalized variance of wind components and temperature are studied within the framework of Monin-Obukhov similarity theory. Heat and momentum fluxes are calculated and compared with other reported values world-wide.

8:26AM C20.00003 Turbulent characteristics analysis of atmospheric surface layer in coastal region of Qatar, YUAN LI, REZA SADR, Texas AM University, College Station — The turbulence characteristics in coastal region of Qatar are analyzed. The micrometeorological data is collected in the coastal site at (26.08N, 51.36E) by three sonic anemometers located on a 9 m height tower from September 2015 to August 2016. The friction velocity, Obukhov length and the normalized variance of wind components and temperature are studied within the framework of Monin-Obukhov similarity theory. During the 1-year measurement period, 33% of data are characterized as stable. The normalized variances are in agreement to empirical fits from other reported values under both unstable and stable atmospheric stratification. However, the normalized variance of stream wise and transverse velocity at near-neutral condition is slightly higher than other observations while the normalized variance of vertical velocity is slightly lower. The measured wind components and temperature in the surface layer shows the sea breeze circulation. The diurnal pattern characteristics in the coastal region is also analyzed for the onshore and offshore breeze.
Similar Across Thermal Regimes

SCOTT SALESKY, University of Oklahoma, WILLIAM ANDERSON, University of Texas at Dallas — Studies of high-Re wall turbulence have revealed the existence of large scale motions (LSMs) that populate the logarithmic region. These motions are often decomposed into balanced and unbalanced components that represent low-frequency and high-frequency waves, respectively. Such decompositions can be defined, for instance, in terms of eigenmodes of a linear operator. Traditionally these decompositions do not account for phase changes of water since these structures become shorter in the streamwise direction and steepen with increasing buoyancy forcing. Using a suite of large eddy simulations of wall-bounded turbulent shear flows with increasingly unstable thermal stratification, we demonstrate how a balanced–unbalanced decomposition can be performed in the presence of phase changes, by including a slow thermodynamic variable involving total water in addition to a slow potential vorticity variable, which are both associated with the nullspace of the linear operator. An IBL, however, is a non-equilibrium phenomena and is yet to be observed to include the fractal structure.

Forcing and shear instability can give rise to quasi-regular vacillation cycles. The framework is applied to two very distinct geophysical systems, the terrestrial tropical cyclone and the martian polar vortex, where diabatic heating is due to the condensation of water vapor or carbon dioxide, respectively, and where eddy transience gives rise to such effects as eye-wall replacement cycles and controls the polar transport of dust and ice aerosols.

8:52AM C20.00005 Characterizing Intermittency in the Stable Arctic Atmospheric Boundary Layer

MOHAMMAD ALLOUCHE, ELIE BOU-ZEID, Princeton University, JOSE FUENTES, Penn State, MARCELO CHAMECKI, UCLA, OTAVIO ACEVEDO, UFSM, SHAM THANEKAR, Penn State, CEDRICK ANSORGE, U of Cologne — To elucidate the physics of surface-atmosphere exchange processes in Polar Regions, our understanding of the stable atmospheric boundary layer (SABL) where buoyancy damps turbulent kinetic energy needs to advance significantly. We seek to understand the intermittent turbulence regime observed in the strongly stable case. The inertial sublayer, referred to as the atmospheric surface layer (ASL), under such regime is characterized by abrupt transitions between turbulent and laminar states. In this study, we analyze field experimental data from Barrow, Alaska to detect intermittent periods based on non-dimensional statistical metrics. We reveal three clusters of turbulence regimes, two of which correspond to the weakly turbulent periods that feature intermittent behavior (cluster 1: intermittent, cluster 2: transitional) and the third cluster is a fully turbulent regime (cluster 3) only mildly damped by stability. We then investigate the origins of the intermittent bursts based on analyses of the Turbulent Kinetic Energy (TKE) budget equation over these bursts in the TKE time series, and assess the combination of velocity and length scales needed in the eddy diffusion theory under intermittent conditions.

1NOAA-CICS

9:05AM C20.00006 Diabatic vortices: a simple framework for tropical cyclones and the martian polar vortex

RICHARD SCOTT, University of St Andrews — The formation and subsequent evolution of annular distributions of potential vorticity, forced by the combination of diabatic heating and the angular momentum transport of secondary, transverse circulations, is investigated in the framework of the forced shallow water equations at various levels of complexity. Annular potential vorticity is found to develop under a range of forcing conditions depending on the radial location of diabatic heating and the structure of secondary circulation; the simplest, axisymmetric formulation of the model allows the effect of the two forcings to be examined in isolation. Further eddy permitting calculations allow the nonlinear transient evolution to be studied, where the competition of forcing and shear instability can give rise to quasi-regular vacillation cycles. The framework is applied to two very distinct geophysical systems, the terrestrial tropical cyclone and the martian winter polar vortex, where diabatic heating is due to the condensation of water vapor or carbon dioxide, respectively, and where eddy transience gives rise to such effects as eye-wall replacement cycles and controls the polar transport of dust and ice aerosols.

9:18AM C20.00007 Balanced and Unbalanced Components of Atmospheric Flows with Phase Changes of Water

LESLIE SMITH, UW-Madison — Atmospheric variables (temperature, velocity, etc.) are often decomposed into balanced and unbalanced components that represent low-frequency and high-frequency waves, respectively. Such decompositions can be defined, for instance, in terms of eigenmodes of a linear operator. Traditionally these decompositions do not account for phase changes of water since the latter create a piecewise-linear operator that differs in different phases (cloudy versus non-cloudy). Here we demonstrate how a balanced–unbalanced decomposition can be performed in the presence of phase changes, by including a slow thermodynamic variable involving total water in addition to a slow potential vorticity variable, which are both associated with the nullspace of the linear operator with phase changes. Evolution of the fast and slow components of water is illustrated in simulations of moist Boussinesq dynamics, as well as in a turbulent steady-state of the idealized Weather Research Forecasting (WRF) model.

1NSF AGS 1443325

9:31AM C20.00008 Morphological Properties of Large-Scale Motions Remain Self-Similar Across Thermal Regimes

SCOTT SALESKY, University of Oklahoma, WILLIAM ANDERSON, University of Texas at Dallas — Studies of high-Re wall turbulence have revealed the existence of large scale motions (LSMs) that populate the logarithmic layer and modulate the amplitude of small-scale turbulent fluctuations near the wall. In flows with unstable thermal stratification, conventional wisdom states that these structures become shorter in the streamwise direction and steepen with increasing buoyancy forcing. Using a suite of large eddy simulations of wall-bounded turbulent shear flows with increasingly unstable thermal stratification, we demonstrate from instantaneous flow visualizations and conditional averages that morphological properties of these structures remain self-similar with increasing unstable thermal stratification. As thermal stratification increases, the downstream edge of an LSM begins to detach from the wall, leaving a wedge of cool, high-momentum fluid beneath. A simple model is developed for the inclination angle of LSMs with increasing thermal instability; atmospheric surface layer observations from the Advection Horizontal Array Turbulence Study (AHATS) are found to be in good agreement with the predicted inclination angles.
is jointly controlled by the droplet-pool viscosity ratio and the droplet Weber number. Speed of the surface-climbing jet is high, i.e., an order one impact event. Besides the classical Worthington jet, there is another jet before the Worthington jet: the liquid in the pool climbs upward during the impact of a viscous droplet on a less viscous pool in a certain range of the Weber number, i.e., two jets appear successively during pool and tune the impact parameters in a wide range to explore the jet phenomena during droplet impact. We found a two-jet phenomenon when a droplet impacts onto a liquid pool. In this experimental study, we increased the viscosity ratio between the droplets and the liquid liquid pools is a ubiquitous phenomenon in nature and many industrial applications. It is widely known that a Worthington jet may be produced with large viscosity ratios, ZHIZHAO CHE, QUAN DING, TIANYOU WANG, Tianjin University — The impact of droplets on

9:57AM C20.00010 Unmanned Aircraft for Mapping Atmospheric Boundary Layer Induced Geomorphological Changes, VICTORIA NATALIE, JAMEY JACOB, Oklahoma State University — The process of acquiring lower atmospheric measurements onboard unmanned aircraft systems (UAS) is becoming a widely available solution. This study ties atmospheric observations using UAS with photogrammetrically mapped rapid geomorphology to observe and relate the terrain induced effects on lower atmospheric phenomena. Lower atmospheric boundary conditions are characterized through wind velocity and turbulence measurements. In order to achieve this data fusion, empirical data was obtained by UAS mounted anemometers and photogrammetric terrain modeling was acquired utilizing airborne imagery. The results of both are analyzed and related to compare the coupled effects. Wind induced terrain variations are also compared through multiple terrain models, showing the temporal evolution of the landscape. This study was performed at Little Sahara, a State park in Oklahoma, a naturally occurring collection of barchan structures and sand dunes that are heavily influenced by the prevailing southern wind. The datasets are months apart, and the changes in the topography demonstrate how closely linked the atmospheric movement and the changes in topography are to each other. Wind observations were made with multiple direct and indirect methods and are presented.

Sunday, November 24, 2019 8:00AM - 10:10AM — Session C21 Drops: Impacts with Liquids I 603 - Jim Duncan, University of Maryland

8:00AM C21.00001 Two-jet phenomenon during the droplet impact on liquid pools with large viscosity ratios, ZHIHAO CHE, QUAN DING, TIANYOU WANG, Tianjin University — The impact of droplets on liquid pools is a ubiquitous phenomenon in nature and many industrial applications. It is widely known that a Worthington jet may be produced when a droplet impacts onto a liquid pool. In this experimental study, we increased the viscosity ratio between the droplets and the liquid pool and tune the impact parameters in a wide range to explore the jet phenomena during droplet impact. We found a two-jet phenomenon during the impact of a viscous droplet on a less viscous pool in a certain range of the Weber number, i.e., two jets appear successively during one impact event. Besides the classical Worthington jet, there is another jet before the Worthington jet: the liquid in the pool climbs upward along the surface of the droplet, and finally collides on the apex of the droplet, resulting in a ‘surface-climbing’ jet. The two-jet phenomenon is jointly controlled by the droplet-pool viscosity ratio and the droplet Weber number. Speed of the surface-climbing jet is high, i.e., an order of magnitude higher than the impact speed.

8:13AM C21.00002 Effects of wind on the generation of secondary droplets and ring waves due to drop impact onto a water surface1, XIANYI LIU, YANG LIU, JAMES H DUNCAN, Department of Mechanical Engineering, University of Maryland, College Park, AIR-SEA INTERACTION TEAM — The effects of wind on the generation of secondary droplets and ring waves during the impact of a single water drop on a deep-water surface are studied experimentally in a wind tunnel that has a test section with a water pool. Experiments are performed by varying impacting drop diameters ranging from 2.0 to 4.0 mm and wind speeds up to 10 m/s. Secondary droplets and ring waves generated during drop impact are measured with a backlit, cinematic shadowgraph technique that employs a high-speed camera. Our experimental results show that after the drop hits the water surface an asymmetrical crown forms on the leeward of the droplet while a wave swell forms on the windward. Secondary droplets are generated from the crown rim. It is found that the diameters and velocities of these secondary droplets are drastically changed with the wind speed. The capillary ring waves on the windward side of the drop impact are stronger than those on the leeward side.

1This work is supported by the Division of Ocean Science, National Science Foundation, under award number 1829943.

8:26AM C21.00003 Understanding thin air film entrapment in drop-pool impact events via numerical simulations1, SHAHAB MIRJALILI, ALI MANI, Stanford University — Experiments have shown that when an O(1mm) water drop impacts a water pool with O(1m/s) velocity, hundreds of micro-bubbles can be entrained in a process known as Mesler entrainment. These bubbles are remnants of a thin extended air film that is entrapped between the two liquid bodies prior to their contact. Despite such observations, neither the details of the mechanism of Mesler entrainment, nor the requirements for it to happen have been established. In this work, we numerically study the impact of a drop on a deep pool to understand the evolution of the liquid surfaces and air film. Our simulations, alongside analytical arguments, lead to the discovery of a capillary transition in the dynamics of the thin air film that allows for formation of high aspect ratio films that can shed micro-bubbles. Based on this observation, we claim that the occurrence of this transition is a trade-off between capillary forces and Van der Waals forces, leading to a criterion for delineating the boundaries of the Mesler entrainment regime in the parameter space. By discovery of scaling laws governing the film thickness after transition, we pave the path for quantitative prediction of the micro-bubbles that are shed as the film retracts after rupture.

8:39AM C21.00004 Impact of immiscible drop onto a pool: jetting and sound generation

ZIQIANG YANG, SIGURDUR T. THORODDSEN, King Abdullah University of Science and Technology — We use high-speed video imaging to study the impact of a perfluorohexane drop on a water pool, with focus on bubble entrainment and fine vertical jetting during the crater collapse. The drop stretches out at the bottom of the crater, before collapsing during its rebound, often entrapping a small bubble inside the drop liquid, or shooting out a fine vertical jet. The entrapment regimes are mapped in the Weber-Froude number space. The size of entrapped bubble scales with impact Weber number. We observe a sequence of critical conditions for the formation of fine jets, which emerge at velocities up to 32 m/s and jet thickness of a few microns, which break up into as many as 50 micro-droplets. The fastest jets, at 45 m/s, occur for a novel multi-dimple crater shape without bubble pinch-off. We also investigate the sound production from the jetting during the crater collapse. The drop stretches out at the bottom of the crater, before collapsing during its rebound, often entrapping a small bubble inside the drop liquid, or shooting out a fine vertical jet. The entrapment regimes are mapped in the Weber-Froude number space. The size of entrapped bubble scales with impact Weber number. We observe a sequence of critical conditions for the formation of fine jets, which emerge at velocities up to 32 m/s and jet thickness of a few microns, which break up into as many as 50 micro-droplets. The fastest jets, at 45 m/s, occur for a novel multi-dimple crater shape without bubble pinch-off. We also investigate the sound production from the bubble oscillations following their pinch-off. By synchronizing hydrophones with the high-speed imaging, we connect the phase of the bubble oscillation with the acoustic signal. We find good agreement with the Minnaert frequency when using the fluid properties of the drop. This applies reasonably well even for very small bubbles where the frequency approaches 100 kHz.

8:52AM C21.00005 Singular jets from the collapse of craters at a pool surface

YUANSHI TIAN, SIGURDUR THORODDSEN, KAUST — The collapse of drop-impact craters can generate a fast singular jet from a dimple which forms at its bottom. A finite-time singularity in the bottom curvature of the crater has in the past been considered as the cause of this singular jet. Self-similar capillary-inertial solutions predict that the radius of the cavity will collapse with time, as \( t \rightarrow 0 \) to the power \( 2/3 \). However, Thoroddsen et al.[1] used a high-speed camera to demonstrate that the final collapse has a power-law closer to a purely inertial collapse, with \( R \sim t^{1/2} \). They also observed no curvature singularity. Herein, we use two synchronized high-speed cameras to study the dimple collapse, at even higher time resolution. One is an ultra-fast camera, capable of up to 5 Mfps, which tracks the crater collapse. The second high-speed camera captures the corresponding speed of the singular jet, at up to 400 kfps. The experiment is performed inside a vacuum chamber to control the ambient pressure. The fastest velocity of singular jets is found to be around 130 m/s and occurs at reduced pressure without crater pinch-off.

KAUST Grant No. URF/1/2621-01-01

9:05AM C21.00006 Study on a vertically falling droplet toward a liquid pool with an inclined bottom wall

YEAWAN LEE, Department of Mechanical Engineering, KAIST, YOUNGDO KIM, Mueunjae School of Undergraduate Studies, POSTECH, HYOUNGSOO KIM, Department of Mechanical Engineering, KAIST — We investigate the evolution of liquid interface deformation after a vertically falling droplet impacts to a liquid pool with an inclined bottom wall. We observed that initially an almost hemispherical cavity was formed, and then asymmetric cavity reversal was observed. Eventually, a tilting jet was measured. For the systematic experiments, substrate angle, depth, droplet diameter, impact velocity, surface tension, and viscosity were varied. We found out that the hemispheric cavity development, which is driven by inertia, is analogous to the impact problems in a deep bath. Next, when the cavity retracts, it shows an oblique conical shape, which is due to the different wave propagation mechanism depending on the bath depth, i.e. a relatively shallow and deep bath. This purely geometry-induced effect causes the tilting jet. Finally, we provided a theoretic model to predict the jet inclination angle by assuming that two different wave propagation competed. Furthermore, we controlled the jet direction by changing the boundary condition of the inclined substrate.

FAN-WEI WANG, CHUN-TI CHANG, National Taiwan University — What happens when a drop impacts a pool with a depth comparable to the drop’s diameter? Through high-speed imaging, our experiments reveal three categories of patterns: fingers at lower impact velocities, flowers at higher impact velocities, and stagnant rings in between. Recent observations will be reported in this talk, together with our characterization by scaling analysis.

9:31AM C21.00008 Direct numerical simulation of rain drop impact on a thin layer of oil over a deep water pool

FRANCIS OGOKE, WOUTER MOSTERT, Princeton University, MARIE-JEAN THORAVAL, Xi’an Jiaotong University, LUC DEIKE, Princeton University — The impact of a water droplet onto a deep pool coated by a film of oil has not yet been thoroughly investigated numerically in the large Weber number range. This process occurs during rainfall on oil slicks at sea, and ejects oily aerosols into the atmosphere that later forms atmospheric particulates. We present direct numerical simulations of the three-phase process using the solver Basilisk. The numerical results are qualitatively and quantitatively compared to existing experimental data, and discuss the influence of numerical resolution on the crown and canopy closure. Finally, the effects of the oil properties and drop shape upon impact on the resulting splash dynamics are investigated.

9:44AM C21.00009 The impact of an oil droplet on oil layers on water bath

DOHYUNG KIM, Sungkyunkwan University, ILDOO KIM, FG Research LLC, JINKEE LEE, Sungkyunkwan University — The impingement of droplets onto another liquid has been investigated under various settings depending on applications. In this work, we investigate the impact of an oil droplet on oil layers on water to simulate the action of the dispersant applied from ship or aircraft to remove the oil contamination on water. Our experiments cover a range of Weber number from 50 to 1000, and we observe the morphological change of the fluid interfaces using the high-speed video imaging. From the image analysis, the length scales of impact craters are measured with respect to the droplet size, the impact velocity, and the thickness of oil layer. Our measurement indicates that the impact dynamics depends on the thickness of oil layer in a non-monotonic manner, which we rationalize using a hypothesized model.

JL thanks to the support by KEITI (2019002790003).
of azimuthal instabilities. and the downward liquid jet that pierces through the bottom of the cavity, are analyzed and discussed, with a specific focus on the inception involved, such as the crown formation above the cavity created by the impact, the ligaments emanating from the rim at the top of the crown, and the downward liquid jet that pieces through the bottom of the cavity, are analyzed and discussed, with a specific focus on the inception of azimuthal instabilities.

**Session C22 Drops: Interaction with Elastic Surfaces, Particles, and Fibers**  
**604 - Farzad Ahmadi, Virginia Tech**

**8:00AM C22.00001 Elastocapillary flow driven blood-plasma separation.**  
**ALWAR SAMY RAMASAMY, ASHIS KUMAR SEN, Indian Institute of Technology (IIT) - Madras — We report a lab-on-a-membrane device which can separate plasma from whole blood due to a combined effect of capillary flow and sedimentation of blood cells. The initial length of the polydimethylsiloxane (PDMS) membrane is made hydrophilic by exposing to oxygen plasma and it is stuck to the PDMS substrate forming a 90° edge. As the dispensed whole blood comes in contact with the membrane, force due to surface tension deflects the membrane and the consequent evolution of blood meniscus results in a Laplace pressure drop that drives the flow. The high velocity gained in the hydrophilic region is sufficient to drive the flow in to the hydrophobic region. As the flow advances, sedimentation of blood cells occurs along the length resulting in cell free layer of plasma. The geometry of the membrane and the hydrophilic length are adjusted such that the time scale required for sedimentation of blood cells is smaller than the flow time scale. As a proof of concept, a detection strip is embedded with the device to detect the level of glucose present in blood plasma.

**8:13AM C22.00002 The droplet on a sugar fiber**

**STEPHANE DORBOLO, FNRS-University of Liege, FLORIANE WEYER, NICOLAS VANDEWALLE, University of Liege, ALEXANDRE DELORY, ESPCI, ESPCI TEAM, FNRS-UNIVERSITE DE LIEGE TEAM — The shape and the motion of a droplet on a fiber are determined by the volume of the droplet, the radius of the fiber and the contact angle (static, advancing and receding) of the liquid on the material of the fiber. We consider a particular case in which the radius of the fiber is modified by the very presence of the droplet. The chosen system consists of a fiber made of glucose on which a water droplet is released. When the fiber is vertical, the droplet slides down the fiber before stopping at the extremity of the fiber. At this point, the droplet dissolves the fiber until the droplet moves upwards. This surprising motion of the droplet is analyzed regarding the dissolution dynamics.**

**8:26AM C22.00003 Redwood-inspired fog harps**

**WEIWEI SHI, THOMAS VAN DER SLOOT, BRANDON HART, BROOK KENNEDY, JONATHAN BOREYKO, Virginia Tech — In California, coastal redwoods (*Sequoia sempervirens*) obtain 34% of their annual hydrologic input from fog drip, as fog droplets are able to effectively slide along the parallel needle arrays to fall onto the soil. Inspired by the redwoods, we recently developed anti-clogging “fog harps” comprised of an array of vertically oriented wires that harvested 2-3X more water compared to traditional meshes during experiments with scale-model in lab. Here, we conduct outdoor field tests for a full-scale fog harp placed side-by-side with a mesh harvester. The harp harvested anywhere from 5X to 70X more water compared to the mesh, depending upon the weather conditions. This enhancement is attributed to the harp’s minimal contact angle hysteresis along the drainage pathway, which completely prevents clogging and even allows for water collection in subpar fog conditions. On the harp, droplets tended to slide along a single wire at a critical volume of only about 0.1 mm³. In contrast, most of the fog collected by the mesh remained pinned, resulting in its gradual evaporation. We expect that the fog harp’s unprecedented collection efficiency will expand the regions where fog harvesting is a viable means of water harvesting.**

**8:39AM C22.00004 Impact and imbibition of blood drops with textiles: Where does this stain come from?**

**DANIEL ATTINGER, RICHARD FAFLAK, Iowa State University — Forensic investigators are sometimes asked if a given stain on fabric could have originated from a blood source at a specific relative location. A wide range of values of the maximum distance that a blood drop can travel have been reported, from less than one meter to more than 10 meters. The formation of bloodstains on fabrics can involve fast atomization mechanisms, flights of deforming droplets, and capillary interactions of a complex fluid with a multiscale substrate. Here we solve the above forensic question with fluid dynamics and inverse data search. Fluid dynamic simulations involve Newton’s equation of motion, models for aerodynamic drag forces on deformable particles, and an in-house capillary model of blood wicking in fabrics. Key parameters are the drop size, launch velocity and launch angle. It is assumed that the ambient air is quiescent, and that stains exhibit similar areas on the front and back of the fabric. The latter assumption is verified for stains larger than the fabric thickness. Simulation results are then mined for the stain size, a parameter directly measurable on a crime scene. Experiments of blood spattered on fabric are in agreement with the simulation results. Findings are presented in a simple chart which discriminates whether a stain of specific size, on a specific fabric, can originate from a blood source at a specific relative location, or not.

A model of droplet durotaxis driven by the elastocapillary response of a soft viscoelastic substrate
dynamic wetting of soft solids has many industrial and biological applications which require a rigorous understanding of the underlying fluid transport mechanism. One such phenomena, known as durotaxis, involves the spontaneous motion of liquid drops on a soft substrate with a thickness gradient. A passive driving force is generated by the elastocapillary deformation of the compliant substrate due to the interaction with the drop. We model the interactions of a two-dimensional drop with a neutrally-wetting viscoelastic substrate with thickness gradient. The substrate response is characterized by a sharp triangular wetting ridge at the contact line whose geometry changes the macroscopic contact angle of the liquid drop from its equilibrium value. The gradient in substrate thickness causes the contact angle to be less on the thicker side, which generates a driving force that moves the drop in the direction of increasing thickness. The drop velocity is determined by the viscoelastic relaxation of the substrate (viscoelastic braking), and computed from a self-consistent model that relates the soft wetting force to the viscoelastic dissipation. We find our results to be in close agreement to the velocities observed in experiment by Style et al. 2013, PNAS.

8:00AM C24.00001 Effect of topology changes on the breakup of a periodic liquid jet, ALBERTO ROMAN-APANADOR, University Of Notre Dame, STEPHANE ZALESKI, Sorbonne Universite, GRETA T. TRYGGVASON, JIACAI LU, Johns Hopkins University — The breakup of a periodic jet is examined computationally, using a front-tracking/finite-volume method, where the interface is represented by connected marker points moving with the fluid, while the governing equations are solved on a fixed grid. Tracking the interface allows control of whether topology changes take place or not. The Reynolds and Capillary numbers are kept relatively low so most of the flow is well resolved. The effect of topology changes is examined by following the jet until it has mostly disintegrated, for different “coalescence” criteria, based on the thickness of thin films and threads. It is found that while the overall breakup is relatively insensitive to the exact conditions for topology changes, various quantitative measures of the evolution are not. The evolution of both two-dimensional and fully three-dimensional flows is examined. It is found that although there is a significant difference between the evolution when no breakup takes place and when it does, once breakup takes place the evolution is relatively insensitive to exactly how it is triggered for a range of coalescence criteria. However, excessively aggressive coalescence leads to different outcomes.

8:13AM C24.00002 A robust multiphase flow solver for high density ratio wave structure interaction problems, AMNEET PAL S. BHALLA, San Diego State University — In this talk, we present a robust, adaptive numerical scheme for simulating high-density ratio and high shear multiphase flows on locally refined staggered Cartesian grids that adapt to the evolving interfaces and track regions of high vorticity. The algorithm combines the interface capturing level set method with a variable-coefficient incompressible Navier-Stokes solver that is demonstrated to stably resolve material contrast ratios of up to six orders of magnitude. The discretization approach ensures second-order pointwise accuracy for both velocity and pressure with several physical boundary treatments, including velocity and traction boundary conditions. To ensure the stability of the numerical scheme in the presence of high density and viscosity ratios, we employ a consistent treatment of mass and momentum transport in the conservative form of discrete equations. We demonstrate through several test cases that the lack of consistent mass and momentum transport in non-conservative formulations, which are commonly used in practice can yield very large numerical error and very poor accuracy for convection-dominant high-density flow regimes. Finally, we combine our robust multiphase fluid solver with an efficient implementation of immersed boundary method to simulate wave-structure interaction problems. Several cases from practical ocean and marine engineering applications, including simulations of wave energy converter devices are presented.

8:26AM C24.00003 Efficient, Discretely Conservative Multi-Material Phase Transport on Unstructured Meshes Using the Interface Reconstruction Library, ROBERT CHIODI, Cornell University, PETER BRADY, NEIL CARLSON, Los Alamos National Laboratory — The Truchas Multiphysics solver was developed at Los Alamos National Laboratory in order to simulate advanced metal casting processes of exotic materials. These processes involve complicated mold geometries that require the use of unstructured meshes in order to adequately resolve the shape of the mold. To enable the accurate simulation of the filling of these molds with liquid metal, we have implemented an unsplit geometric multi-material volume of fluid method capable of individually tracking the many constituent ingredients involved in metal casting. This was done using a newly developed, open-source library, the Interface Reconstruction Library, which handles the difficult computational geometry and interface reconstruction methods needed in geometric volume of fluid methods. In this talk, we will detail how to implement an efficient algorithm for discretely conservative multi-material phase advection on unstructured meshes. Its computational performance and solution accuracy on both hexahedron and tetrahedron meshes will be compared to the current state-of-the-art for a suite of canonical test cases. This abstract is approved for release under LA-UR-19-27091.

8:39AM C24.00004 Two-way coupled Euler-Lagrange simulations with particles and mesh spacing of arbitrary sizes, BEREND VAN WACHEM, FABIAN DENNER, FABIEN EVRARD, Otto-von-Guericke University Magdeburg — The Euler-Lagrange (EL) approach is widely used to simulate particulate flows, because of the relatively low computational cost and the straightforward modelling of particle-particle interactions. Since relying on an assumption of separation of scales between the general features of the flow (resolved on the underlying fluid mesh) and those at the scale of the particles (not resolved on the mesh), the EL method typically requires tracked particles to be much smaller than the grid cells in which the flow equations are solved, commonly referred to as the “particle-in-cell” approach. For the cases that require high fluid mesh refinement, this can strongly limit the size of the particles that can be accurately tracked. In this work, we propose an EL approach that alleviates the particle size restrictions. It relies upon the filtering of the flow equations with a particle marker function; a process in which a length-scale is chosen. We also present a model for the reconstruction of the undisturbed flow velocity and volume fraction at the particle locations, based on the study of the flow through a regularised momentum source and/or a volume fraction dimple. The ability of the proposed framework to accurately track particles of arbitrary sizes is shown with an array of test-cases.

8:52AM C24.00005 A hybrid PIC-DEM approach for multi-phase computational fluid dynamics, ROBERTO PORCU, ANN ALMGREN, MICHELE ROSSO, Lawrence Berkeley National Laboratory, JORDAN MUSSER, National Energy Technology Laboratory, WILLIAM FULLMER, National Energy Technology Laboratory; Leidos Research Support Team, ANDREW MYERS, OSCAR ANTEPARA, Lawrence Berkeley National Laboratory — MFiX-Exa is a new code being developed by the National Energy Technology Laboratory and Lawrence Berkeley National Laboratory as part of the U.S. Department of Energy’s Exascale Computing Project. MFiX-Exa originated by combining the discrete element method (DEM) modules of the classic MFiX code (mfix.netl.doe.gov) with a modern low Mach number projection method for the continuous fluid phase. The new algorithm is implemented using the AMReX software framework for massively parallel block-structured applications (amrex-codes.github.io). Despite the ever-increasing computational power offered by world-leading supercomputers, DEM is still prohibitively expensive for the modeling of large industrial-scale problems. Other methods, as particle-in-cell (PIC), are less computationally intensive, but they tend to be less accurate than DEM. In this work, we exploit the efficiency of PIC and accuracy of DEM to introduce a hybrid multi-phase PIC-DEM approach. Overall, the strategy relies on applying the PIC model to particle-dense regions while keeping the DEM model for the dilute parts of the domain. Within this setup, the modeling of the PIC/DEM transitions is proposed. The method and results are to be presented in the context of chemical loop reactors simulations.

1This research was supported by the Exascale Computing Project (17-SC-20-SC), a collaborative effort of the U.S. Department of Energy Office of Science and the National Nuclear Security Administration.
Simulation, YUNCHAO YANG, S. BALACHANDAR, University of Florida — We developed a highly scalable immersed boundary
method (IBM) algorithm for multiphase flow simulation. In particular, a Double Bin Ghost Particle (DBGP) algorithm is designed to obtain the
distributed data storage and scalable data transferring features for the particle phase. The proposed algorithm uses a New Queen/Worker data
structure to indicate the particle-level and marker-level quantities and communications. In the DBGP algorithm, each particle is represented
by a queen marker and surface worker markers. The queen marker determines the motion and total force of a particle. The worker marker
performs the fluid-particle interaction, including velocity interpolation and force projection. A double binning system is determined through the
Cartesian binning of the physical domain to relate each MPI rank with its overlapping bins. By searching the bin-to-rank map, all remote MPI
ranks influenced by the local particle can be readily identified. The ghost queen marker is generated in the remote MPI rank based on the local
queen marker and the queen binning structure, and same for the ghost worker maker. Experimental results show that the algorithm is efficient
and scalable on large-scale computations.

Techniques for sharp numerical simulations of incompressible
multiphase flows1. RAPHAEL EGAN, FREDERIC GIBOU, University of California, Santa Barbara — We present recent progress
and developments to enable numerical simulations of incompressible two-phase flows in a fully sharp fashion, avoiding smearing of any fluid
properties across interfaces. We use distributed adaptive cartesian Quadtree/Octree grids with a levelset method to represent the interface(s).
The ability to solve elliptic interface problems with sharp jump conditions and discontinuous coefficients is essential to such applications. We
discuss the corresponding numerical challenges and illustrate them with respect to the governing jump conditions and the balance of viscous
stress across the interface. We present numerical methods to address these challenges and to ensure accurate solutions in infinity norm (i.e.,
even for points close to the interface) for accurate interface transport.

Numerical simulations of the full ink-jet printing processes: From
jetting to evaporation1. CHRISTIAN DIDDENS, YAXING LI, TIM SEGERS, University of Twente, HANS REINTEN, YOURI
DE LOORE, HERMAN WIJSHOFF, Oc-Technologies B.V., DETLEF LOHSE, University of Twente — Ink-jet printing requires to perfectly
control both the jetting of droplets and the subsequent droplet evaporation and absorption dynamics. Considerable complexity arises due to
the fact that ink is constituted of a mixture of different liquids, surfactants and pigments. Using a sharp-interface ALE finite element method, we
numerically investigate the main aspects of ink-jet printing, both on the jetting side and on the drying side. We show how a short pause
in jetting can result in clogged nozzles due to solvent evaporation and discuss approaches how to prevent this undesired phenomenon. Once
the droplets have been jetted on paper and is evaporating, the print quality can be deteriorated by the well-known coffee-stain effect, i.e., the
preferential deposition of particles near the rim of the droplet. This can be prevented in several ways, e.g., employing controlled Marangoni flow
via surfactants or co-solvents or printing on a primer layer jetted in beforehand, thus creating a homogeneous deposition pattern for a perfect
final printout.

This work is part of an Industrial Partnership Programme of the Netherlands Organisation for Scientific Research (NWO), which is
co-financed by Oc-Technologies B.V., University of Twente, and Eindhoven University of Technology.
A Numerical Formulation to Study Interactions Between Fluids and Deforming Solid. JIAZHEN QIAO, AMIR RIAZ, University of Maryland, College Park, AKASH DHURU, ELIAS BALARAS, George Washington University — In the present work, level set formulations are used to track solid-fluid interface as well as to track a dynamic grid which captures solid deformation. The solid is assumed to be viscoelastic and a unified framework of equation of motion is used to solve for both solid and fluid dynamics. Fluid-Structure Interaction is accounted for by using an external body force term to enforce no-slip boundary condition at the interface and an elastic stress term to impose elastic stress boundary condition at the interface. The elastic stress term is implemented through a pressure jump which corrects the pressure distribution as well as the velocity field in the computational domain as a result of the presence of the elastic solid. The proposed method has an advantage of robust implementation in three dimensions and has the potential of incorporating different viscoelastic models to account for various material properties.

8:13 AM C25.00002 Advancements to a Dual-Scale approach for Simulating Turbulent Phase Interface Interactions. DOMINIC KEDELTY, MARCUS HERRMANN, THOMAS ZIEGENHEIN, Arizona State University — Direct Numerical Simulation remains an expensive task for atomization simulations. To decrease the burden of DNS, a dual-scale modeling approach (Gorokhovski and Herrmann, 2008) that describes turbulent phase interface dynamics in a Large Eddy Simulation framework to study the evaporation process of a liquid in an inert gas using the volume of fluid method. The proposed methodology successfully addresses the two main challenges in performing direct numerical simulation of phase-changing flows when a whole-domain formulation is adopted: the interface-normal velocity jump and the accurate calculation of the interfacial mass-flux exchanged between the two phases. The former is handled by constructing a continuous and divergence-free liquid velocity field, which is used to compute the interface velocity, while the latter is accomplished by reconstructing a level-set function. This resolved realization is maintained using a Refined Local Surface Grid approach (Herrmann, 2008) employing an unsplit geometric Volume-of-Fluid method (Owkes and Desjardins, 2014). Advection of the phase interface on this DNS scale requires a reconstruction of the fully resolved interface velocity. In this work, results from the dual-scale LES model employing sub-filter turbulent eddy reconstruction by combined approximate deconvolution and non-linear spectral enrichment (Bassenne et al. 2019) and sub-filter surface tension model (Herrmann 2013) are compared to DNS results for a phase interface in a homogeneous isotropic turbulent flow at two different Weber numbers.

The support of NASA TT grant NNX16AB07A is gratefully acknowledged.

8:26 AM C25.00003 A volume of fluid method for interface-resolved simulations of evaporating flows. NICOLÒ SCAPIN, PEDRO COSTA, LUCA BRANDT, Kungliga Tekniska högskolan — We developed a numerical framework to study the evaporation process of a liquid in an inert gas using the volume of fluid method. The proposed methodology successfully addresses the two main challenges in performing direct numerical simulation of phase-changing flows when a whole-domain formulation is adopted: the interface-normal velocity jump and the accurate calculation of the interfacial mass-flux exchanged between the two phases. The former is handled by constructing a continuous and divergence-free liquid velocity field, which is used to compute the interface velocity, while the latter is accomplished by reconstructing a level-set function. This resulting approach is built on top of an efficient, FFT-based two-fluid Navier-Stokes solver coupled with an algebraic volume of fluid method (MTHINC), and extends with the corresponding transport equations for the vaporized liquid mass and thermal energy. The method was thoroughly tested against benchmarks of increasing complexity, which show its excellent mass conservation properties and good overall performance.

8:39 AM C25.00004 Quadric interface reconstruction from volume fractions for curvature estimation. AUSTIN HAN, OLIVIER DESJARDINS, Cornell University — In this talk, we present a new method for evaluating the curvature of a captured interface in the context of volume of fluid (VOF). This method endeavors to fit a paraboloid to the interface using only volume fraction data in a neighborhood of cells. It shares strong similarities with the height-function (HF) method, which also represents the interface as a paraboloid. But because the HF method orients the paraboloid along the directions of the underlying Cartesian mesh, its accuracy deteriorates severely in cases of poorly resolved slanted interfaces. In contrast, we allow here for the paraboloid to be arbitrarily rotated and propose a method for evaluating the volume of each cell capped by the arbitrary paraboloid. We verify the performance of this approach on a range of canonical problems, paying special attention to the dependence of the error on the alignment of the interface with the mesh. Finally, we discuss the extension of this method to unstructured meshes.

On algebraic TVD-VOF methods for tracking material interfaces. SERGIO PIROZZOLI, SIMONE DI GIORGIO, Sapienza University of Rome, Department of Mechanical and Aerospace Engineering, ALESSANDRO IAFRATI, CNR-INSEAN, Istituto Nazionale per Studi ed Esperienze di Architettura Navale — We revisit simple algebraic VOF methods for advection of material interfaces based of the well established TVD paradigm. We show that greatly improved representation of contact discontinuities is obtained through use of a novel CFL-dependent limiter whereby the classical TVD bounds are exceeded. Perfectly crisp numerical interfaces are obtained with very limited numerical atomization (flotsam and jetsam) as compared to previous SLIC schemes. Comparison of the algorithm with accurate geometrical VOF shows larger error at given mesh resolution, but comparable efficiency when the reduced computational cost is accounted for.

This work has been financially supported by the Flagship Project RITMARE The Italian Research for the Sea, coordinated by the Italian National Research Council and funded by the Italian Ministry of Education, University and Research within the National Research Program 20142015.

9:05 AM C25.00006 Height-function method for curvature estimation on two- and three-dimensional non-uniform Cartesian grids. FABIEN EVRARD, FABIEN DENNER, BEREND VAN WACHEM, Otto-von-Guericke University Magdeburg — Estimating the curvature of an interface from the corresponding discrete indicator function field is known as one of the main challenges associated with the simulation of interfacial flows with surface tension. The sharpness of the discrete indicator function renders classical differenciation approaches ineffective (understand: divergent) as the mesh resolution is increased. Out of all the methods available in the literature, the height-function (HF) method is the sole example of a curvature estimation technique that converges with mesh refinement and has been shown to exhibit performances that are superior to other approaches when coupled to a multiphase flow solver. Although a second-order accurate general formulation for non-uniform Cartesian grids has been derived for the two-dimensional case, the three-dimensional HF formulas have so far been limited to uniform Cartesian grid configurations, where they correspond to classical finite difference formulas. This work presents an extension of the well-known height-function curvature estimation method to non-uniform Cartesian grids, both for the two- and three-dimensional cases. The convergence of the method is studied through its application to known analytical surfaces, and ways to improve its order are discussed.
9:18AM C25.00007 A diffused-interface approach for simulating compressible multiphase flows within an adaptive mesh refinement framework, KARTHIK KANNAN, Arizona State University, FABIAN FRITZ, NICO FLEISCHMANN, Technical University of Munich, CARLOS BALLESTEROS, MARCUS HERRMANN, Arizona State University — A diffused-interface method for solving the compressible, multicomponent Navier-Stokes equations, i.e. the quasi-conservative five-equation model (Allaire et al., 2002) including capillary and viscous effects (Coralic and Colonius, 2014, Garrick et al., 2017) is used in conjunction with a novel, unstructured, cell-based adaptive mesh refinement (AMR) library (Ballesteros, 2019). Low dissipation, high spatial resolution is obtained by using a WENO-Z (Borges et al., 2008) discretization, while the numerical smearing of the material interface is controlled using a THINC scheme (Shyue and Xiao, 2014). This ensures higher-order while limiting the material interface width to 2-3 mesh cells. Surface tension effects are incorporated by means of a modified HLLC solver (Garrick et al., 2017). Curvature is computed using a stretched variant of the standard height function method (Cummings et al., 2005) to account for the smearing of the material interface. The use of AMR helps achieve higher mesh resolution in regions of liquid and shock discontinuities, which is crucial to compressible atomization applications. Results for test cases ranging from shock-interface interaction to liquid atomization are presented.

9:31AM C25.00008 Surface tension effects on the evolution of interfaces in multi-material compressible flows, PEDRAM BIGDELOU, PRAVEEN RAMAPRABHU, University of North Carolina at Charlotte — We report on the effect of surface tension on the evolution of perturbed material interfaces in compressible multimedium flows. The level set method is used to track the interface, while the real Ghost Fluid Method1 (gFGM) captures the interfacial coupling between the fluids. We implement these techniques in an in-house code IMPACT, designed for simulation of compressible flows with shocks and material interfaces. We present various test problems to address how surface tension affects the growth of perturbed interfaces driven by shocks. In particular, we examine surface tension effects on the baroclinically driven Richtmyer-Meshkov instability.2,3 The 2D simulations were initialized with a sinusoidal perturbation imposed at the interface. An incident shock crosses the interface, followed by the growth of the imposed perturbation. The simulations were conducted at different values of the surface tension, and the variation in the instability growth rate was compared with recently proposed models.2 Wang C.W., Liu T.G., Kho P.C., SIAM J. 9:57AM C25.00010 Non-local surface tension model for N-phase flows1, AMANDA HOWARD, ALEXANDRE TARTAKOVSKY, Pacific Northwest National Laboratory — We propose a nonlocal model for surface tension obtained in the form of an integral of a molecular-force-like function added to the Navier-Stokes momentum conservation equation for N-phase fluid flows. We demonstrate that our model recovers both microscale and macroscale features of multiphase flow, eliminating the need for expensive hybrid MD-NS models, and providing strong advantages for modeling multiphase flows at length scales not feasible with MD simulations. We present benchmark cases for the nonlocal model with comparisons to the level set method for N-phase flows and fluid-fluid-solid flows. Results are shown to be in agreement with analytical and previous numerical results.

Sunday, November 24, 2019 8:00AM - 10:10AM — Session C26 Drag Reduction II

8:00AM C26.00001 Drag reduction of three-dimensional riblets on a flat plate turbulent boundary layer1, GIOACCCHINO CAFIERO, GAETANO IUSO, Politecnico di Torino — We performed an experimental investigation of the turbulent flow on a flat plate presenting micro roughness. In addition to the typical longitudinal micro-grooves, commonly referred to as riblets, we also investigate the performance of three-dimensional riblets, i.e. presenting a sinusoidal pattern. Further to the typical cross-section parameters that characterize longitudinal riblets, namely depth (h) and spacing (s) of the micro grooves, the sinusoidal riblets add two more parameters: the wavelength (λ) and the amplitude (A). In our study, we consider a parabolic profile (s/h=0.7) for the cross-section of the micro-grooves and we study two different sinusoidal riblets varying the amplitude (A=0.6mm and A=0.15mm), for a fixed value of the wavelength λ/s=64mm. Our load cell measurements show a consistent effect of the amplitude of the sinusoidal riblets on the friction drag reduction. In particular, while the longitudinal riblets feature drag reductions of the order of 7.7% at s/h=13 (in good agreement with Bechert et al. 1997), the sinusoidal riblets can achieve values as large as 10% for similar values of s/h. Stereoscopic-PIV measurements show the different near wall structure of the flow, when the three-dimensional riblets are employed.

8:13AM C26.00002 Streamwise evolution of drag reduced turbulent boundary layer with dilute polymer solutions, YASH SHAH, SERHIY YARUSEVYCH, University of Waterloo — The effect of dilute polymer solutions on the evolution of flat-plate turbulent boundary layer has been investigated experimentally. Three different injection concentrations of 100, 500 and 1000 ppm of polyethylene oxide (PEO) were injected through an inclined slot on the plate and particle image velocimetry measurements were performed to characterise boundary layer development and compare the results to the baseline cases without injection and with water injection. Drag reduction (DR) was found to decrease approximately linearly with injection distance for all injection concentrations. The results show that polymer injection has a significant effect on the flow statistics, including the extent of viscous sublayer and the characteristics of the log layer. The polymer injection also attenuates peak velocity fluctuations and moves them away from the wall with increasing polymer concentration. It is also shown that the ejection and sweep motions are weakened notably by polymer injection.

8:26AM C26.00003 Passive Actuation of Scales Modeled after Shark Scales to Delay Separation in a Steady Turbulent Boundary Layer1, CHASE PARSONS, AMY LANG, LEONARDO SANTOS, ANDREW BONACCI, SARAH FOLEY, The University of Alabama — Delaying the onset of flow separation is of great interest in the field of fluid mechanics to improve the overall aerodynamic efficiency of aircraft. This project seeks to investigate passive flow control using shortfin mako shark inspired manufactured scales in turbulent boundary layer separation. Previous studies have demonstrated the effectiveness of similar devices placed inside the separation bubble. In this study, the scales are placed in front of the separation point to investigate the effectiveness to delay separation. Reversing flow is the primary mechanism causing the actuation of the shark scales, so under these test conditions, it is hypothesized that reversing flow low speed streaks can actuate and be controlled by the scales, thus delaying the onset of separation. To generate a controlled adverse pressure gradient, a rotating cylinder induces separation at a chosen location within a flat plate turbulent boundary layer ranging from Re=495,000 to Re=710,000. With this thick boundary layer, DPIV is used to measure the flow characteristics. The goal is to better understand the fundamental mechanisms by which shark scales can induce passive flow control with the aim of fabricating surfaces suitable for real aircraft applications.

8:39AM C26.00004 Flow mechanism at the interface layer of the bio-inspired coated surface in a turbulent channel flow , VENKATESH PULLETKURTHI, CARLO SCALO, LUCIANO CASTILLO, Purdue University — We have investigated the turbulent channel flow coated with bio-inspired surface via fully unstructured Pseudo-spectral method. The present study is inspired by the denticles present on the skin of the mako shark. Previous experimental studies by Bocanegra et. al (2018) revealed that the denticle like micro structures (85 μm) delayed the separation in an adverse pressure gradient flow. However, in spite of several studies to understand the flow near the wall, the interaction at the interface layer and inside the microstructures is not fully understood. Here, we use high resolution adaptive mesh refinement based DNS simulations to resolve the flow in the interface layer and inside the microstructures to shed light on the mechanism between the interface layer which is responsible for the drag reduction and/or delay in separation. This study also will help to model the interface layer boundary conditions for numerical modeling.

8:52AM C26.00005 Deviations in Polymer Drag Reduction Performance with Mechanical Degradation1, ZEESHAN SAEED, YASAMAN FARSIANI, DR. BRIAN ELBING, Oklahoma State University — Polymer drag reduction studies, although show great promise in flow control applications, are significantly limited by a problem; mechanical degradation of polymers in shear flows. Insights into this problem were made by comparing the drag reduction performance (slope increments on Prandtl-Karman (P-K) plots) of Polyethylene oxide (PEO) samples with and without degradation. The molecular weights of PEO samples—a measure of the extent of their degradation—were determined by matching the onset of drag reduction i.e. the intersection of the polymeric curve with the Prandtl-von Karman law on the P-K plots. Range of mean molecular weights (0.6 – 8 million g/mol) of PEO samples were included in the test matrix. Higher molecular weight samples were mechanically degraded to lower mean molecular weights that matched the molecular weights of available non-degraded samples (e.g. 4 million g/mol was degraded to 0.6 million g/mol). Comparisons of resulting slope increments determined from P-K plots of the degraded and non-degraded samples were then scaled with a function based on their mean molecular weights to show how polydispersity is central in determining the flow characteristics. This presentation reports the findings from the experiments and analysis mentioned above.

9:05AM C26.00006 Drag-reduction curves for anisotropic permeable substrates1, GARAZI GOMEZ-DE-SEGURA, RICARDO GARCIA-MAYORAL, University of Cambridge — We present DNSs of channel flows bounded by modelled streamwise-preferential permeable substrates. The resulting drag curves are similar to those of riblets. For small permeabilities, the curves exhibit a linear regime, where drag reduction is proportional to the difference between the streamwise and spanwise permeabilities. This breaks down for a critical value of the wall-normal permeability, beyond which spanwise-coherent, Kelvin-Helmholtz-like structures develop, and the performance begins to degrade. We present simple linearised models to predict both the linear regime and its breakdown, which yield accurate a priori estimates for the substrates’ performance. The largest drag reduction observed in our DNSs is ≈ 20 – 25% at a friction Reynolds number Reτ = 180, at least twice that obtained for riblets.

9:18AM C26.00007 Role of wall-attached structures in frictional drag reduction by streamwise1, MIN YOON, HYUNG JIN SUNG, KAIST — The role of wall-attached structures in the frictional drag reduction by the Navier slip is explored. The wall-attached structures are extracted from the clusters of streamwise velocity fluctuations in a turbulent channel flow (Reτ = 470). The skin friction coefficient (Cf) is decreased by 35%. A dataset of the no-slip condition (Reτ = 577) is also included for comparison. The wall-attached structures extend toward the upstream in the vicinity of the wall by the slip. The convection velocity of the wall-attached structures increases near the wall, leading to the wide influence on the inner region via roll-cell motions. The vortical structures circumscribing the wall-attached structures are attenuated, since the mean shear of the structures is decreased by the slip. The contribution of the wall-attached structures to Cf is quantified through the skin friction decomposition, which can be derived from the mean vorticity equations. The advective vorticity transport and vortex stretching terms around the wall-attached structures are found to dominate the contributions to the frictional drag. The wall-attached structures are responsible for 53.2% of the total reduction of Cf.

The Baseball Seam: Clever and Capable Passive Flow Control
BARTON SMITH1, ANDREW SMITH2, Utah State University — It is obvious to any observer of baseball that the aerodynamics of the ball are important, both for pitched and batted balls. Much has been written about the well-known Magnus Effect, or the force on a moving ball due to its rotation. Less is known about forces due to the wake of the ball. Baseball seams make baseballs very interesting when compared to other sports balls. They play two roles: As many have speculated, when located in the favorable pressure gradient on the front of the ball, they can cause laminar flow to become turbulent, which subsequently modifies the wake of the ball. More surprisingly, when located in the adverse gradient on the back of the ball, they can also modify the location of boundary layer separation and can make the wake (and thus the force on the ball) asymmetric, leading to movement. In this talk, we will discuss these effects and the possibility of the existence of the “laminar express” 2-seam fastball that moves due an asymmetric wake rather than by Magnus effect.

Passive control of vortex-induced vibration of a sphere,1, ANCHAL SAREEN2, University of Minnesota, JOHN SHERIDAN, KERRY HOURIGAN, MARK THOMPSON, Monash University — Although passive methods for controlling vortex-induced vibrations (VIV) are extensively studied for a circular cylinder, such methods remain unexplored for a basic three-dimensional bluff body, a sphere. In this study, we use a sphere trip wire as a passive method to control sphere VIV. The effect of a surface trip is experimentally investigated for varying diameter (1.25 x 10^-2 < k/d < 6.63 x 10^-2) and stream wise location (φ = 20° -70° from the stagnation point) of the trip wire for a wide range of reduced velocities (3 < U* < 20). It was found that the vibration amplitude decreases progressively with the increase in the stream wise location angle (φ) of the trip wire. The control was highly effective in mode II and mode III of the VIV response with maximum reduction of up to 97.8% for φ = 60°. Interestingly, thicker trip wires (k/d > 1.25 x 10^-2) were more effective in mode I, but showed a galloping response for higher reduced velocities.

Underlying Mechanisms of Drag Reduction in Turbulent Flows1, ALEX ROGGE, JAE SUNG PARK, University of Nebraska - Lincoln — Turbulent flow control is of great importance in fundamentals and applications due to the potential benefits associated with it, particularly regarding drag reduction for energy savings. In this study, we will investigate three strategies to better understand their underlying mechanisms for drag reduction in turbulent channel flows. These strategies include using a spanwise body force, adding a small concentration of long-chain polymers into the fluid, and using a superhydrophobic surface on the channel walls. Direct numerical simulations were performed to elucidate the mechanisms at play. Analysis is based on the lifetime of turbulent phases represented by the active and hibernating phases of minimal channel turbulence (Xi and Graham PRL 2010). Given similar drag reduction percentages, the polymer and slip cases show similar mechanisms, while the body force case shows a different mechanism. The polymers and slip surfaces cause hibernating phases to happen more frequently, while the phase duration remains almost constant. The body forces prolong the duration of hibernating phases, while these phases become less frequent. Lastly, these drag reduction mechanisms and their various behaviors with respect to control parameters will be further discussed and analyzed.

Session C27 Biological Fluid Dynamics: Swimming, Sensing, Navigating

Development and validation of a bio-inspired, self-propelled metachronal swimming robot1, ARVIND SANTHANAKRISHNAN, MITCHELL FORD, Oklahoma State University — Metachronal swimming is a method of drag-based locomotion used by crustaceans such as krill, mysids, and shrimp. Studies of metachronal swimming can help in understanding ecologically important daily vertical migrations of these organisms and their hydrodynamic signaling mechanisms. We developed a robotic model ("krillbot") and validated its performance using published data on Pacific and Antarctic krill. Dynamic scaling was used to design the krillbot body and test conditions. The krillbot was suspended in an 8-foot long tank filled with water-glycerin mixture, and was allowed to self-propel on an air bearing. Time-resolved PIV measurements during self-propulsion showed that interaction of shear layers of adjacent paddles resulted in the formation of a continuous jet moving in the caudoventral direction. Swimming speed and orientation of the jet varied with phase lag and paddling frequency. Displacement efficiency and Reynolds number based on swimming speed were found to fall within the range observed in freely swimming krill.

Importance of appendage spacing in metachronal swimming1, MITCHELL FORD, ARVIND SANTHANAKRISHNAN, Oklahoma State University — Drag-based metachronal paddling of multiple appendages is a common swimming strategy used by numerous aquatic animals (such as copepods, krill, and comb jellies) across a wide range of Reynolds numbers. These organisms have been reported to have a narrow range of dimensionless appendage spacing (ratio of inter-appendage spacing to appendage length) between 1/5 and 2/3 (Murphy et al., Mar. Biol. 158, 2011). Small inter-appendage spacing could allow for synergistic interaction of shear layers formed by paddling of adjacent appendages, whereas large inter-appendage spacing could effectively isolate individual appendages from each other. Using a robotic metachronal swimming model ("krillbot"), we investigated the effects of varying appendage spacing on propulsive forces, swimming speed, and wake characteristics for appendage spacings both within and greater than the biological range. Swimming speed was found to increase both with closer spacing of padding appendages and with increasing paddling frequency. PIV-based flow visualization results will be presented.

8:26AM C27.00003 Hydrodynamics of caridoid escape response in krill. ANGELICA CON-NOR, D. ADHIKARI, DEVESH RANJAN, D.R. WEBSTER, Georgia Tech — Krill are shrimp-like crustaceans and are a keystone species in many deep-water food webs. Due to their abundance and sensitivity to changes in the environment, there are many studies on krill ecology. But, there is limited quantitative analysis of the hydrodynamics of their locomotion and biomechanics. The length of Antarctic krill can range 2-6 cm, and these animals typically swim in a low to intermediate Reynolds number (Re) regime. The caridoid escape response, a maneuver unique to jumping arthropods, occurs when the minimal abdominal flexions resulting in powerful backward strokes. For the first time, the propulsion behavior and flow disturbance of a caridoid escape response performed by an Antarctic krill (Euphausia superba) has been quantified. A high-speed tomographic Particle Image Velocimetry (tomo-PIV) system quantifies three-dimensional flow fields around a free swimming E. superba and its wake. The specimen is roughly 3 cm in length and by using this tail flipping mechanism, it is able to accelerate backwards increasing its speed by 2 orders of magnitude in an interval of 0.025 s to a maximum speed of 25 cm/s. The data from these flow fields are used to calculate the changes in the velocity and vorticity field shedding light on both the flow behavior in this Re regime and intricacies of the bio-locomotion of zooplankton.

8:39AM C27.00004 Can the copepod seta sense the hydrodynamic disturbance of prey entrained in the feeding current? XINHUI SHEN, MARCOS MARCOS1. Nanyang Technological University, HENRY FU, University of Utah — The prey detection of feeding-current feeding copepods is achieved by beating their cephalic appendages to generate flow entrainment and utilizing their mechanoreceptive setae to sense the presence of the prey. The hydrodynamic characteristics of the copepod’s feeding current have been extensively studied; however, there is little knowledge on if the copepod seta is capable of sensing the hydrodynamic disturbance of prey, or otherwise a direct contact of the setae and prey is required. Here we present a mechanical model to examine the deformation mechanics of the copepod setae when subjected to the flow disturbance of an inert particle entrained in the copepod’s feeding current. We first determine the hydrodynamic characteristics of a copepod and beating stroke of its cephalic appendages through video analysis, and utilize the immersed boundary method to solve for the flow fields around the seta with and without the presence of the entrained prey. We then proceed to evaluate the setal deformation induced by such flows, and demonstrate that the flow disturbance induced by the entrained prey leads to a different setal deformation pattern, which may be sensed by the copepod.

8:52AM C27.00005 Non-axisymmetric flow and sensing around copepods. JULIAN HACHEMEISTER, DAISUKE TAKAGI, University of Hawaii at Manoa — Microscopic organisms generate a variety of viscous flow fields which are critical for locomotion, feeding, and sensing. We report on a simplified model of the flow field generated by a feeding copepod while sinking, swimming and hovering. In each case, we compare the different flow fields and compute the strength of the hydromechanical signal due to any suspended particle. Among the three modes, hovering is most effective in bringing in a fresh supply of nutrients from its surroundings. Our study shows an approximate range in which a copepod may sense its prey and the role mechanical sensing plays in feeding.

9:05AM C27.00006 Numerical investigation of seal whiskers in distinguishing the patterns of wakes induced by moving objects with different shapes. GENG LIU, QIAN XUE, XUDONG ZHENG, University of Maine — Phocid seals are able to use their whiskers (or vibrissae) to detect and track artificial and biogenic hydrodynamic trails. Well trained seals are even able to discriminate the size and shape of upstream moving objects through their wakes. The present study employs a one-way coupling model of flow-structure interaction (FSI) to investigate the hydrodynamic mechanism of the wake discrimination. The root mechanical signals of whisker arrays in the wakes induced by different moving objects are simulated and analyzed in detail. It is found that the signal patterns of whisker arrays are associated with the strength and the direction of the jets induced by the 3D vortices in the wake. The distinct signal patterns enable the seal to discriminate the shapes of upstream moving objects. In addition, a theoretical model is built to decoding the relationship between the location of the disturbance source and the sensed flow information.

9:18AM C27.00007 A 3D computational fluid dynamics study of the swimming of the larva of mosquito (Chironomus plumosus). BOWEN JIN, Beijing Computational Science Research Center, HAOXIAO LUO, Vanderbilt University, YANG DING, Beijing Computational Science Research Center — The larva of Chironomus plumosus has a cylindrical body with a length about 14mm. Experiments have shown that it swims by periodically bending its body into a circle (the head and tail nearly in touch) and then unfolding it. However, the propulsion mechanism of the larva is not well understood. Here we use 3D computational fluid dynamics to simulate the swimming of the larva. According to the experimental observations of the movement pattern, the centerline curvature $k$ is prescribed in the form of a sinusoid function. The rotational and translational velocities are obtained by coupling the body with the fluid. The simulation results show that the greatest force and thrust are generated on the head and tail during the unfolding stage. By adjusting the time fraction $\gamma$ of the unfolding stage, we find that both the swimming speed and the energetic efficiency increase with decreasing $\gamma$. However, the difference in swimming speed is only significant at intermediate Reynolds number (Re=1000). When Reynolds number increases (Re=3000) or decreases (Re=30), the difference in speed becomes smaller. Our study suggests that the kinematics of the larva of mosquito is specialized for swimming at intermediate Reynolds numbers.

9:31AM C27.00008 Elastic hoops jumping on water: drag-dominant model of water-jumping arthropods. HAN BI JEONG, Seoul National University, EUNJIN YANG, Korea Institute of Science and Technology Evaluation of Planning, YUNSUK JEUNG, Seoul National University, JULIETTE AMAUGER, Ecole Normale Superieure, HO-YOUNG KIM, Seoul National University — Some remarkable milli-scale organisms jump from the water surface using surface tension, such as the well-studied water strider. Larger arthropods, however, require a greater force to complete the same task. In the case of fishing spiders, a pressure drag, rather than capillary forces, is utilized to propel the spiders’ bodies into a successful jump. Such a strategy is also discriminated from the unsteady added inertia effects employed by a basilisk lizard, a water-walking reptile. Here, we present a mathematical model of thin elastic hoops jumping on water, inspired by the fishing spider. A pre-deformed hoop coated with superhydrophobic particles floating on water shows similar dynamic conditions to that of the jumping mechanics of fishing spiders. When released, the water applies a force against the deforming hoop, dominantly in the form of drag, propelling the hoop into the air. By combining the vibration model of the elastic hoop and the time-varying drag forces induced by fluid motion, we accurately predict the trajectory and jump efficiency of the hoops. This work can be used to develop large-scale water-jumping robots and to understand the water-jumping mechanics of large semi-aquatic arthropods.
9:44AM C27.00009 Swimming and settlement of coral larvae on structured surfaces in unsteady shear flow , DANIEL GYSBERS, MARK LEVENSTEIN, GABRIEL JUAREZ, University of Illinois at Urbana-Champaign — The large and amazing structures that we know as coral reefs have humble beginnings as tiny (<1 mm) swimming organisms. Coral larvae must navigate the vast marine environment to locate a suitable surface where they will permanently settle on by responding to various chemical, biological, and physical cues. We present experimental results of coral larval swimming and settlement on varying structured surfaces in unsteady shear flow. Our experiments use PTV of swimming larvae and PIV of unsteady shear flow in a U-shaped oscillatory flume to investigate the effect of hydrodynamic interactions between coral larvae and local flow structures generated by surface topology on settlement rates.

9:57AM C27.00010 Role of large-scale advection and small-scale turbulence on the vertical migration of gyrotactic swimmers , CRISTIAN MARCHIOLI, University of Udine, GAETANO SARDINA, Chalmers University of Technology, LUCA BRANDT, Linn FLOW Centre and SeRC, KTH Mechanics, ALFREDO SOLDATI, TU Wien — We use DNS-based Eulerian-Lagrangian simulations to investigate the dynamics of small gyrotactic swimmers in free-surface turbulence. Swimmers are characterized by different vertical stability: some realign with a characteristic time smaller than the Kolmogorov time scale, $\tau_K$, while others possess a re-orientation time longer than $\tau_K$. We cover one order of magnitude in the flow Reynolds number, and two orders of magnitude in the stability number, which measures bottom heaviness. We observe that large-scale advection dominates vertical motion when the stability number, scaled on the local Kolmogorov time scale, is above unity: This leads to enhanced migration towards the surface, particularly at low Reynolds number, when swimmers can rise through surface renewal motions that originate from the bottom-boundary turbulent bursts. Small-scale effects become important when the Kolmogorov-based stability number is below unity: Migration towards the surface is hindered, particularly at high Reynolds, when bottom-boundary bursts are less effective in bringing bulk fluid to the surface. We demonstrate that a Kolmogorov-based stability number around unity represents a threshold beyond which swimmer capability to reach the surface and form clusters saturates.

Sunday, November 24, 2019 8:00AM - 10:10AM –
Session C29 Biological Fluid Dynamics : Phonation and Speech 611 - Michael Krane, Penn State University

8:00AM C29.00001 Control volume analysis of phonatory aerodynamics using velocity and pressure measurements1 , TIMOTHY WEI, University of Nebraska, HUNTER RINGENBERG, University of Colorado - Boulder, NATHANIEL WEI, Stanford University, DYLAN ROGERS, University of Nebraska, FEIMI YU, LUCY ZHANG, Rensselaer Polytechnic Institute, MICHAEL KRANE, Penn State Applied Research Lab — In a collaborative effort, flow through simplified models of human vocal folds are being examined both experimentally and computationally. The experimental work described in this talk entails a 10x scaled-up model in a free surface water tunnel. In addition to the 10x physical scale, the reduced kinematic viscosity of water allows for a 1500x reduction in frequency to match the Reynolds numbers and reduced frequencies of human phonation. As such DPIV measurements, coupled with time resolved pressure measurements along the vocal fold model, have sufficiently high spatial and temporal resolution to accurately study the dynamics and energetics of the underlying fluid dynamics. This, in turn, provides direct linkage with aerodynamics analyses done using a matching computational model. In this study, we use integral control volume analysis in both the scaled-up physical experiment and the computational model to examine the momentum and energy balance in the flow. Specific analysis of the Bernoulli equation for a range of Reynolds numbers and reduced frequencies will be examined. Comparison with computational results and observations on the key phenomena related to phonation will be provided.

1Support from NIH R01DC005642 is appreciated.

8:13AM C29.00002 Vocal Fold Trauma: Deleterious Compensatory Behaviors in Response to Benign Lesions1 , MOHSEN MOTIE-SHIRAZI, BYRON ERATH, Clarkson University — Abnormally high vocal fold (VF) contact pressures result in the formation of benign lesions such as polyps and nodules, which may produce highly asymmetric VF motion, disrupt glottal aerodynamics, and prevent VF closure. In response, compensatory behaviors, such as increasing the subglottal pressure, are often performed to maintain acoustic output. It is hypothesized that increased subglottal pressure leads to a deleterious cycle of higher contact pressure, and subsequently, additional VF trauma. The objective of this work is to quantify VF contact pressures during this common compensatory behavior. Four-layer synthetic VF models are fabricated and investigated in a hemilaryngeal configuration with the wall contact pressure measured at the midpoint of the VF contact zone. Three sizes of lesions are modeled by inserting a spherical ball in the mid anterior-posterior direction of the superficial lamina propria, below the epithelium. Contact pressure and radiated acoustic sound pressure level (SPL) are first measured in normal models with no lesion and then compared to those with a lesion, where the subglottal pressure is adjusted to match the radiated SPL between the two cases. Results demonstrate that localized lesion stiffness and compensations via subglottal pressure significantly alter the VF kinematics, producing much higher contact pressures that increase with lesion size.

8:26AM C29.00003 Reduced-order glottal airflow model enhanced by machine learning , ZHENG LI, YE CHEN, HAOXIANG LUO, Vanderbilt University — Complementary to expensive 3D flow simulations, reduced-order glottal airflow models are useful in the simulation of vocal fold vibration for various purposes such as tissue property identification and optimization of surgical implants. Existing reduced-order models are typically based on the Bernoulli principle and have limited accuracy. In recent works, we have developed a novel one-dimensional flow model including pressure loss along the glottis and also the entrance effect. The model has shown advantages over the Bernoulli based model. In this work, we introduce machine learning to enhance this one-dimensional flow model. In particular, we firstly perform 3D fluid-structure interaction (FSI) simulation for vocal fold vibrations with different vocal fold stiffnesses and medial thicknesses. Using the 3D data, sparse regression is performed to estimate the loss coefficient and entrance effect parameter for the reduced-order flow model. We then combine this enhanced reduced-order flow model with 3D FEM tissue model to simulate the vocal fold vibration. In comparison with full 3D FSI model, very good agreements are achieved in terms of vibration amplitude, frequency, as well as phase delay of the medial surface in all cases considered.
8:39AM C29.00004 Acoustic coupling effect on glottal dynamics during phonation.1, DARUISH BODAGHI, WEILI JIANG, QIAN XUE, XUDONG ZHENG, University of Maine — In this study, a two-dimensional flow-structure-acoustics interaction computational model was utilized to examine the effect of the acoustic coupling on glottal dynamics during normal human phonation. An incompressible Navier-Stokes equation based flow solver, three mass based vocal fold model and a hydro/acoustic splitting method based acoustics solver were coupled for simulating the three-way interaction. The hydro/acoustic splitting method is first verified for low Mach number wall bounded flow against compressible N-S solutions obtained by using Fluent. Two simulation cases, with and without the acoustic coupling, were studied to identify the role of the acoustic coupling in normal phonation. The results indicate that, while the incompressible flow model could roughly capture basic glottal dynamics, the acoustic coupling has noticeable effects on both glottal flow and vocal fold dynamics.

8:52AM C29.00005 A framework for simulation of sibilant fricatives using implicit compressible flow solver. HSUEHJUI LU, CHUNGANG LI, Kobe University, AKIYOSHI IIDA, TSUKASA YOSHINAGA, Toyohashi University of Technology, KAZUNORI NOZAKI, Osaka University, MAKOTO TSUBOKURA, Kobe University — A numerical framework for modeling the sibilant fricative production is built in this study. The implicit time scheme with immersed boundary method based on a hierarchical structure grid as well as the modified solution-limited time stepping method for the compressible flow are adopted. Firstly, the acoustic resonance generated from the flow around the single plate is simulated to validate the numerical scheme and the result shows that this framework is highly efficient and suitable for the massive parallelization system to tremendously save the calculation time. Then, the simulation for a simplified model of the sibilant /s/ is conducted and SPL profiles are in good agreement with the experimental results. Finally, the simulation for a realistic geometry of sibilant /s/ scanned from the human vocal tract is performed to demonstrate that this framework is capable of making a contribution to the dental treatment in the near future.

9:05AM C29.00006 Phonation energy budget computed from high-fidelity aeroelastic-aeroacoustic simulation1, LUCY ZHANG, FEIMI YU, Rensselaer Polytechnic Institute, MICHAEL KRANE, ARL, Pennsylvania State University — A rigorous accounting of phonation energy utilization is presented, using high-fidelity computer simulations. The simulation uses the modified immersed Finite Element (iFEM) formulation, supplemented by boundary condition control using Perfectly Matched Layers. Vocal folds mimic the swept-ellipse multilayer rubber model used in coordinated experiments. Simulations were run for a range of subglottal pressures. Simulation results are used to compute terms of the integral energy equation for the volume containing air in the larynx. Flow work terms in particular are decomposed to clarify power transfer mechanisms. The mechanism described by each energy equation term is then classified in terms of its role (input, output, loss). Laryngeal acoustic efficiency is also presented.

1NIH R01DC005642

9:18AM C29.00007 Phonation aeroacoustic sources identified from simulation1, FEIMI YU, LUCY ZHANG, Rensselaer Polytechnic Institute, MICHAEL KRANE, Applied Research Laboratory, Penn State University — The principal aeroacoustic sources in phonation are estimated from a high-fidelity computer simulation. The simulation uses an immersed Finite Element (iFEM) formulation, supplemented by boundary condition control using Perfectly Matched Layers. Vocal folds mimic the swept-ellipse multilayer rubber model used in coordinated experiments. Simulations were run for a range of subglottal pressures. For each simulation, the principal aeroacoustic sources were deduced: a volume source due to changes in vocal fold volume, and a dipole source associated with vocal fold drag. Recent arguments regarding the equivalence of vocal fold drag and transglottal pressure force, and the relationship between vocal fold drag and glottal volume flow are also evaluated.

1NIH R01DC005642

9:31AM C29.00008 2. Simultaneous measurements of vocal fold wall motion, aerodynamic and acoustic pressure, and volume flow1, FAITH BECK, PAUL TRZCINSKI, ADAM NICKELS, ZACHARY YOAS, JEFF HARRIS, MICHAEL KRANE, Applied Research Laboratory, Penn State University — Simultaneous measurements of acoustic pressure, transglottal pressure, volume flow, and vocal fold surface motion are reported. Measurements were conducted in a hemilarynx configuration consist of the Penn State Upper Airway Model (PSUAM), using a multilayer swept-ellipse vocal fold model. Pressure and volume flow measurements were conducted as described in other studies in the PSUAM, but vocal fold surface motion was also acquired by imaging the surface with three Vision Research v1212 high-speed cameras. The surface motion was estimated from the video using DaVis Strainmaster. Vocal fold motion is decomposed using POD and correlated to pressure and flow measurements.

1Acknowledge NIH R01DC005642 and Penn State ARL (IRAD)

9:44AM C29.00009 Vocal fold asymmetry effects on phonation aeroacoustic source strengths1, PAUL TRZCINSKI, ZACHARY YOAS, MICHAEL KRANE, Applied Research Laboratory, Penn State University — Measurements of aeroacoustic source strengths in a physical model of the human airway are taken for variations in prephonatory mechanical symmetry. Opposing synthetic silicone vocal folds were placed in the Penn State Upper Airway Model (PSUAM) and subjected to various driving pressures for which fold oscillations occur. Vocal fold symmetry was varied by changing the multilayer structure between the two vocal fold models. For each vocal fold pair, measurements include unsteady transglottal pressure, acoustic pressure in the vocal tract and trachea regions, projected glottal area, and time-varying volume flow. In particular, transglottal pressure has been shown to be an accurate measure of vocal fold drag, the aeroacoustic source strength. Measuring vocal fold drag indicates how asymmetry affects phonatory sound production.

9:57AM C29.00010 4. Phonation energy utilization and vocal efficiency estimated from measurements in a physical model of the human vocal system¹, MICHAEL KRANE, PAUL TRZCINSKI, ZACHARY YOAS, Applied Research Laboratory, Penn State University — Measurements performed in the Penn State Upper Airway Model of acoustic pressure, transglottal pressure, volume flow, and glottal area are presented. These are used to estimate flow work terms of the integral energy equation, applied to the vocal system, to identify principal power transfers during phonation. These terms are estimated for the larynx, vocal tract, and complete system. Each power flow is then classified as an input, output, or loss mechanism, according to the sign of the average power transfer per cycle. Efficiencies for each subsystem, and the system as a whole, are then presented as the ratio of output to input power per cycle.

Session C30 Biological Fluid Dynamics : Cardiovascular Flows  612 - Jian-Xun Wang, University of Notre Dame

8:00AM C30.00001 Multiscale modeling of the cardiovascular deconditioning during spaceflight, STEFANIA SCARSOGLIO, CATERINA GALLO, LUCA RIDOLFI, Politecnico di Torino, Torino, Italy — Permanence in microgravity characterizing long-term spaceflights causes a general deconditioning of the cardiovascular system. A constellation of hemodynamic mechanisms - such as fluid shift, blood volume reduction, vessel elasticity changes, and cardiac atrophy - concurs to define a 0G adaptation point, which is identified by an overall relaxation of the cardiovascular system. This scenario promotes orthostatic intolerance on reentry and poses open questions on re-adaptation for spaceflights beyond 1 year. We here present a computational approach to compare the cardiovascular response in supine position on Earth and at 0G adaptation point during spaceflight. The proposed aim is twofold: (i) understand the underlying mechanisms leading to cardiovascular deconditioning; (ii) describe the hemodynamics of districts for which clinical data are not always feasible and accurate even on Earth. The present approach relies on a validated multiscale modeling of the cardiovascular system combining a 1D description of the arterial tree together with a lumped parameterization of the remaining regions (i.e., venous return, heart chambers, pulmonary circulation, baroreceptor regulation).

8:13AM C30.00002 Rich Dynamic Behaviors of Self-excited Oscillation of Collapsible Channel¹, QIUXIANG HUANG, FANG-BAO TIAN, JOHN YOUNG, JOSEPH C. S. LAI, The University of New South Wales, FLOW SCIENCE LAB TEAM — Fluid-structure interaction (FSI) in collapsible channel flow is numerically studied with an immersed boundary-lattice Boltzmann method. Compared with previous studies, current method is able to simulate nonlinear fully coupled FSI in two-sided collapsible channel and high Reynolds numbers flow (Re up to 2000). The stability of the hydrodynamic flow and collapsible channel walls are examined for a wide range of Reynolds numbers, structure-to-fluid mass ratio, external pressure and wall thickness. Based on the numerical simulations, we (i) explore the physical mechanisms responsible for the onset of self-excited oscillations, and (ii) characterise the chaotic behavior of the collapsible channel walls. Rich dynamic behaviors of self-excited oscillation are observed. Regarding point (i), we identify that the flow bifurcate to bistable mode at Re=320 due to the symmetry breaking as the increase of Reynolds number. Besides, the external pressure applied on the elastic beams plays an important role in triggering the self-excited oscillation of the beam. And then for point (ii), the existence of chaotic behavior of the collapsible channel walls is confirmed by a very positive dominant Lyapunov exponent and the chaotic attractor in the velocity-displacement phase portrait.

8:26AM C30.00003 Optogenetics-Biofluid Model for Engineered Beating Cardiomyocytes using Meshfree Method, YASSER ABOELKASSEM, University of California San Diego — Optogenetic techniques make use of genetically encoded, light sensitive ion channels to manipulate cellular function with light. More recently, microbial opsins such as the light-gated ion channel channelrhodopsin-2 (ChR2) have been transfected into cardiomyocytes, allowing cardiac muscle contractions to be initiated by pulses of light. Cardiac optogenetics raises numerous interesting possibilities, including optical pacemakers, defibrillators, and flow pumping assistant devices accomplished through the precise spatiotemporal application of light excitations. In this study, an optogenetics-fluid mathematical model is proposed to study the flow motions induced by a single engineered cardiac cell. The optogenetics module is based on Monte Carlo type of simulations to control light stimulus events, which are then used to probe the cellular wall contractions. The fluid module is derived based on a two-dimensional meshfree-Stokeslets computational framework. The results show that, cells with a slightly different beating profile can induce different flow field that is characterized by coherent vortices with different strengths and core sizes. This implies that, each cell induces unique flow biomarker “signature”, which can be used to better understand the intrinsic sub-cellular excitation-contraction processes of cardiac cells.

8:39AM C30.00004 A Multi-fidelity Ensemble Kalman Method for Inverse Problems in Cardiovascular Flows, HAN GAO, JIAN-XUN WANG, University of Notre Dame — In cardiovascular modeling, parameters associated with boundary conditions and mechanical properties are often unknown or uncertain, which can be calibrated using indirect and/or sparse clinical measurements based on data assimilation (DA) techniques. The ensemble Kalman filter (EnKF), as a derivative-free DA approach, has started to gain popularity for solving inverse problems in physiological modeling. However, the computational cost of the EnKF could be considerably high due to a large ensemble of costly forward simulations, in particular when the iterative Kalman updates are needed for nonlinear inversion (i.e., iterative ensemble Kalman method). In this work, we propose an efficient multi-fidelity ensemble Kalman inversion approach, where both the low- and high-fidelity forward models are utilized to accelerate the statistical convergence. Moreover, to improve the identifiability of the parameters to be inferred, additional physical/physiological constraints will be imposed by re-weighting the ensemble members in a Bayesian manner. Numerical examples of vascular flows in patient-specific geometries are presented to demonstrate the effectiveness and merit of the proposed framework.
8:52AM C30.00005 Super-resolution and Denoising of Flow MRI Data using Physics-Constrained Deep Learning , LUNING SUN, JIAN-XUN WANG, University of Notre Dame — The recent advances in the flow magnetic resonance (MR) imaging enable noninvasive and in vivo measurement of the blood flow velocity field. However, the resolution and signal-to-noise ratio (SNR) of flow MR images still remain the limiting factors in clinical practice. This is especially true when investigating small vascular structures such as intracranial aneurysms or treating near-wall regions where wall shear stress is calculated. Therefore, super-resolution and denoising of flow fields from MR images are of great importance and remain active research areas. In this work, we propose an innovative deep learning framework to upscale low-resolution flow fields and to reduce the measurement noise using physics-constrained deep neural networks (DNN). Specifically, a generative DNN will be trained on the low-resolution data to capture the flow field. In the meantime, the violation of physical laws will be penalized on a large number of spatiotemporal points where measurements are not available and noises are expected to be reduced. The trained generative model can reconstruct the flow field with arbitrarily high resolution. Several test cases with synthetic vascular flow data are studied to demonstrate the merit of the proposed method.

9:05AM C30.00006 Comparison of Multi-scale Models for Blood Flow in Zebrafish Brain1, MINGLANG YIN, Center for Biomedical Engineering, Brown University, USA, XIAONING ZHENG, Division of Applied Mathematics, Brown University, USA, ANSEL BLUMERS, Department of Physics, Brown University, USA, HIROYUKI NAKAJIMA, Department of Cell Biology, National Cerebral and Cardiovascular Center Research Institute, Japan, YOSUKE HASEGAWA, Institute of Industrial Science, The University of Tokyo, Japan, GEORGE KARNIADAKIS, Division of Applied Mathematics, Brown University, USA — The contribution of hemodynamics in developing zebrafish vasculature has long been recognized as one of the main factors in the mechanisms of vessel pruning. Using the modern computational fluid dynamics models, such as the three-dimensional (3D) Navier-Stokes model, the one-dimensional (1D) blood flow model, or the Dissipative Particle Dynamics (DPD), we performed the first detailed simulations to investigate the hemodynamics in zebrafish hindbrain. The simulations were performed on the same zebrafish hindbrain vasculature with the same Dirichlet boundary condition at its inlet. The flow rate and pressure profiles at outlets and inner points show a good agreement between the 1D and the other two models. This validates the 1D model accuracy in simulating blood flow at low Reynolds. Further investigations on non-Newtonian effect are ongoing. The performance of the 1D model facilitates its applications to further investigations on transport properties in physiological processes such as angiogenesis in zebrafish vasculature, mouse retinal plexus, or even a tumor.

9:18AM C30.00007 From whole-organ imaging to in-silico blood flow modeling: a new multi-scale network analysis for revisiting tissue functional anatomy1, FRANCK PLOURABOUE, Fluid Mechanics Institute of Toulouse UMR CNRS-UPS-INPT, J. COLOMBELLI COLLABORATION, C. BARreau, C. Guissard, L. Teysedre, J. Rouquette, A. Lorsignol, Louis Castella Collaboration, P. Kennel, J. Dichamp Team — We present a multi-disciplinary image-based blood flow perfusion modeling of a whole organ vascular network for analyzing both its structural and functional properties. We show how the use of Light-Sheet Fluorescence Microscopy (LSFM) permits whole organ micro-vascular imaging, analysis and modelling. By using adapted image post-treatments workflow, we could segment, vectorize and reconstruct the entire micro-vascular network composed of 1.7 millions vessels, from the tissue-scale, inside a ∼ 25 × 5 × 1 = 125 mm³ volume of mouse fat pad, hundred time larger than previous studies, down to the cellular scale at micron resolution, with the entire blood perfusion is modeled. Adapted network analysis revealed the structural and functional organization of mouse-scale tissue as strongly connected communities of vessels. These communities share out a distinct heterogeneous core region and a more homogeneous peripheral region, consistently with known biological functions of fat tissue. Graph clustering analysis also revealed two distinct robust meso-scale typical sizes (from 10 to several hundred times the cellular size), revealing, for the first time, strongly connected functional vascular communities. These communities networks support the reduced-order model can be constructed directly through the Jacobian matrix in the CFD solver. Reasonable accuracy and computational efficiency are demonstrated by comparing the reduced-order model result with the reference CFD result.

9:31AM C30.00008 Reduced-order modeling of flow in the circulatory system, CHENWEI MENG, MAHDI ESMAILY, Sibley school of mechanical and aerospace engineering, Cornell University — Lumpped parameter networks (LPN) coupled with 3D CFD simulations provide a mean to simulate the flow in the circulatory system at a reasonabe accuracy and affordable cost. In this method, the flow in major vessels is fully resolved, whereas it is modeled in the rest of the circulatory system using lumped components. Despite these attractive properties, the usage of 3D-LPN coupling method is hindered by need for reverse-engineering the LPN components through a tuning process, which itself requires performing many CFD simulations. To reduce the cost of such expensive calculations, a reduced-order model is introduced to replace the 3D model that is orders of magnitude less expensive to solve. The introduced reduced-order model is constructed using a circuit network analogy that can capture flow inertial and viscous losses in the 3D fluid domain. Additionally, we show that the reduced-order model can be constructed directly through the Jacobian matrix in the CFD solver. Reasonable accuracy and computational efficiency are demonstrated by comparing the reduced-order model result with the reference CFD result.

9:44AM C30.00009 Characterization of Flow Mediated Dilation via a Physics-Based Model, BCHARA SIDNAWI, Villanova University, ZHEN CHEN, CHANDRA SEHGAL, University of Pennsylvania, SRIDHAR SANTHANAM, QIANHONG WU, Villanova University, CELLULAR BIOMECHANICS AND SPORTS SCIENCE LABORATORY TEAM, DEPARTMENT OF RADIOLOGY AT THE UNIVERSITY OF PENNSYLVANIA TEAM — In this work, a preliminary physics-based model describing the transient behavior of the brachial artery during the Flow Mediated Dilation (FMD) test, is developed. Experimental diameter over time data were collected, via in-vivo ultrasound imaging. The model, which also accounts for mechano-transduction, was able to capture a key feature of the experimentally observed responses which a conventional viscoelastic model fails to explain. Characteristic dimensionless groups quantifying the physical state of the artery emerged from the model. The values of these dimensionless quantities, that predicted a response that best matched the experimental counterpart to a specific artery, were considered the values characterizing it. The meaning of these parameters and how they can be related to the cardiovascular health are discussed and explained. The transient physics manifested in the two-way Fluid-Structure Interaction (FSI) driving the FMD process, present an interesting opportunity to explore the nature of living materials making up the arterial walls, which would in turn lead to a better understanding and therefore detection of the onset of some forms of Cardiovascular Disease (CVD).
9:57AM C30.00010 Towards Blood Flow Velocimetry with X-Ray CT. BRENDAN COLVERT, ERIC YU, FRANCISCO CONTIJOCHE, ELLIOT MCEVIEGH, University of California San Diego — Cardiovascular disease (CVD) is a tremendous burden in terms of morbidity, mortality, and costs to the healthcare system. Various forms of CVD including atherosclerosis, valve and ventricular dysfunction, aneurysms, and thrombogenesis are associated with localized blood flow abnormalities. Accordingly, the ability to noninvasively interrogate physiological flows enables identification and diagnosis of disease, monitoring of therapies, and research on the hemodynamics of CVD. In the clinic, blood flow measurements are primarily made using phase contrast magnetic resonance imaging (PC-MRI) and ultrasonic color Doppler imaging. Certain limitations of these techniques for patients who have contraindications or suffer from arrhythmias, as well as the desire for volumetric flow information necessitate the development of a new modality for blood flow velocimetry. In this work, we propose a strategy to optimally integrate imaging data from contrast-enhanced X-ray CT scans with flow solvers. We evaluate the effectiveness of this strategy in the context of a simplified flow model. Our initial findings provide insight into the theoretical foundations of the proposed technique and lay the groundwork for further research on the use of X-ray CT for blood flow velocimetry.

Sunday, November 24, 2019 8:00AM - 10:10AM – Session C31 Biological Fluid Dynamics: Active Fluids

8:00AM C31.00001 Transport control for apolar active suspension in a rectangular channel using circular cylinders. SHENG CHEN, TONG GAO, MICHIGAN STATE UNIVERSITY, COMPLEX FLUIDS GROUP AT MSU TEAM — We study the control for transport of a dilute apolar active suspension in a rectangular channel using circular cylinders. We adopt a coarse-grained active liquid crystal model to describe collective unstable dynamics of non-motile but mobile rod-like particles, i.e., the “Extensors”, in Stokes flows. By using a Galerkin mixed finite element method, we previously revealed various patterns of spontaneous coherent flows that can be unidirectional, traveling-wave, and chaotic for the case without cylinders inside. To uncover the transport control using circular cylinders, we first study how fixed cylinders change the flow transitions in channel by systematically changing the cylinder size, separation distance, and the channel width. We further study if the flow transitions alter when the cylinders are free to rotate about a fixed axis.

8:13AM C31.00002 Chaotic mixing of an active nematic in viscous environments. AMANDA TAN, KEVIN MITCHELL, LINDA HIRST, University of California, Merced — The unifying theme of active matter is that collections of subunits consume energy locally, translate that energy into movement, and ultimately produce large-scale flows. Such materials are out of equilibrium systems. A fascinating example of a tunable non-equilibrium system is the microtubule/kinesin-based active nematic that forms at an oil/water interface. This material, based on biological polymers and molecular machines, produces a steady-state in which we observe moving topological defects that braid around one another. Defects are continuously created and annihilate, generating fluid flows. A direction of interest in non-equilibrium systems is to study how the active material responds to changes in its environment. To generate external environmental changes, we change the viscosity of the oil that the network is in contact with and probe subsequent changes in the morphology and speed of the network. Lower viscosity oils give rise to higher defect densities, lower defect densities, and vice versa for higher viscosity oils. Using analysis from chaotic advection theory, we explore how environmental changes affect various quantitative parameters such as the local fluid stretching rates within the network and the topological entropy as calculated from defect braiding.

8:26AM C31.00003 Stress relaxation in active suspensions. PRABHU NOTT, Indian Institute of Science, SANKALP NAMBIAR, Jawaharlal Nehru Centre for Advanced Scientific Research, PHANI KANTH SANAGAVARAPU, Indian Institute of Science, GANESH SUBRAMANIAN, Jawaharlal Nehru Centre for Advanced Scientific Research — The rheology of ‘active’ suspensions has been a subject of considerable interest in recent years, but mostly under steady shear. In a recent experimental study [1], the response of a dilute suspension of E. coli was characterized for impulsive initiation and cessation of shear. Interesting features in the relaxation of the shear viscosity were found, as the shear rate was varied, including regimes of apparent superfluidity. Here, we report a theoretical study that attempts to explain and analyze the observed rheological response [2]. Starting from a kinetic equation appropriate for rod-shaped bacteria like E. coli, we determine the evolution of the orientation distribution as a function of time following a step change in the shear rate, and thereby, the temporal evolution of the shear viscosity. One of the most striking aspects of such properties is the recent experimental observation of a vanishingly small shear viscosity in suspensions of swimming bacteria. Here, we present our recent results on the connection between this phenomenon and the onset of collective motion in bacterial suspensions. We find that confinement strongly influences both phenomena, and that the apparent viscosity drops to zero before the transition to collective motion. We compare our predictions against the active gel theory, and discuss their relevance to recent experiments.

1National Institutes of Health (NIH) K01 HL 143113-01 to F.J.C. and R01 HL 144678 to E.R.M. UCSD Institute of Engineering in Medicine (IEM) 2017 Galvanizing Engineering in Medicine (GEM) Award to E.R.M.

8:39AM C31.00004 Self-propulsion of active colloids via ion production. MARCO DE CORATO, XAVIER ARQU, TANIA PATIO, Institute for Bioengineering of Catalonia (IBEC), MA ARROYO, LaCN, Universitat Politècnica de Catalunya, SAMUEL SNCHEZ, Institute for Bioengineering of Catalonia (IBEC), IGNACIO PAGONABARRA, Universitat de Barcelona — Active particles that harness chemical energy from the environment and turn it into directed motion attracted great interest in the recent years. Several applications have been envisaged for these particles from pollutant removal to anti-cancer therapies. To optimize active colloids for advanced applications, one has to achieve fundamental understanding of their dynamics in fluidic environments. Here, we develop a model for the self-propulsion of a chemically active colloid that asymmetrically releases ionic species. By solving the relevant equations using simulations and a perturbation expansion, we evaluate the velocity of the active particle as a function of the main parameters. Our results highlight several novel aspects that are qualitatively different from other mechanisms. The active particle can reverse direction of motion by changing the salt concentration in the solution and can propel even if it is not charged. We find an optimal condition for self-propulsion and a novel regime in which the velocity is independent of the ionic strength of the environment. The model quantitatively captures the salt-dependent velocity measured in experiments using active colloids that propel by decomposing urea via enzymatic reaction.

8:52AM C31.00005 'Superfluid’ vs collective motion in model active suspensions. ALEXANDER MOROZOV, VIKTOR ŠKULTETY, School of Physics & Astronomy, University of Edinburgh, UK — Systems comprising active particles often exhibit non-zero steady-state currents, and possess unique mechanical and transport properties that are absent from their passive counterparts. One of the most striking examples of such properties is the recent experimental observation of a vanishingly small shear viscosity in suspensions of swimming bacteria. Here, we present our recent results on the connection between this phenomenon and the onset of collective motion in bacterial suspensions. We find that confinement strongly influences both phenomena, and that the apparent viscosity drops to zero before the transition to collective motion. We compare our predictions against the active gel theory, and discuss their relevance to recent experiments.
Two separate mathematical models are proposed to study these behaviors. The formation of microtubule network and its uniform contraction. The second phase is dominated by the steady state flow established afterwards.

In this talk, we use an optically-controlled active matter system, consisting of stabilized microtubule filaments and kinesin motors, to demonstrate a series of systems of biological or synthetic molecules are capable of spontaneously organizing into structures and generating global flows while lacking segregation, movement) by organizing the activity of force-generating, active molecules in time and space. Most experimental active matter systems of biological or synthetic molecules are capable of spontaneously organizing into structures and generating global flows while lacking the spatiotemporal control found in cells, limiting their utility for studying non-equilibrium phenomena and bioinspired engineering. Here, we show how to use this method to simulate deformable droplets of active fluids. When multiple drops are immersed in a Stokesian fluid, their melting is a complex phenomenon. Here we investigate the formation and melting of a nonequilibrium crystal, an active vortex crystal, in a minimum continuum model for active matter. Using simulations, we find spontaneously emerging vortex crystal solutions after an extended turbulent transient. These active vortex crystals melt into a turbulent active fluid as the activity or the advection, the two free parameters in the model, are changed. We map out the phase diagram and systematically characterize the melting transition as a function of both the parameters. Depending on the path through the parameter space, the melting exhibits diverse transition scenarios; it may proceed through a hysteretic marginal stability region or an intermediate hexatic phase. Our results indicate that crystalline phases in active matter share similarities with their equilibrium counterparts.

Two-dimensional crystals show several intriguing properties. For instance, crystals in equilibrium systems lack long-range positional order and their melting is a complex phenomenon. Here we investigate the formation and melting of a nonequilibrium crystal, an active vortex crystal, in a minimum continuum model for active matter. Using simulations, we find spontaneously emerging vortex crystal solutions after an extended turbulent transient. These active vortex crystals melt into a turbulent active fluid as the activity or the advection, the two free parameters in the model, are changed. We map out the phase diagram and systematically characterize the melting transition as a function of both the parameters. Depending on the path through the parameter space, the melting exhibits diverse transition scenarios; it may proceed through a hysteretic marginal stability region or an intermediate hexatic phase. Our results indicate that crystalline phases in active matter share similarities with their equilibrium counterparts.

9:31AM C31.00008 Experimental characterization and modeling of contractile behavior and fluid flows in an optically-controlled microtubule network

8:00AM C32.00001 High-accuracy simulations of thousands of deformable, interacting, active droplets
Speaks to swimming and crawling near surfaces with rough boundaries. To the direction of undulatory waves on the body, and body rotation, and depends critically upon the distance to the wall(s). The theory also

SPAGNOLIE, University of Wisconsin-Madison — Surfaces with anisotropic mobilities present an intriguing opportunity for passively influencing driven flow. For the vortex flow, we investigate the effects of SwIMs that encircle the vortex centers. We also test predictions of chaotic trajectories of active tracers in the flow. For the hyperbolic flows, we investigate the structure of the barriers as a function of the imposed flow magnitude. Vortex chain flows. We test theories that predict “swimming invariant manifolds” (SwIMs) that act as one-way barriers that impede the motion of active tracers in the flow. In the hyperbolic flow, we investigate the structure of the barriers as a function of the imposed flow magnitude. For the vortex array, we find both regular and chaotic trajectories of swimmers, including trajectories that exhibit long-range transport. This stands in stark contrast to passive tracers in the same flow, which move on localized, regular orbits when the flow is time-independent. The SwIMs are shown to form leaky one-way barriers to swimmers, and we identify additional phase-space structures—namely, periodic orbits and invariant tori—which regulate the chaotic transport of swimmers throughout the vortex array.

Merced, TOM SOLOMON, Bucknell University — We present experiments on the effects of imposed, laminar fluid flows on the motion of active (self-propelled) tracers. The active tracers are bacillus subtilis bacteria, including a wild-type strain and two variations, one with the GFP mutation and one with a smooth-swimming mutation for which the microbe doesn’t tumble. The imposed flows are simple hyperbolic flows and vortex chain flows. We test theories that predict “swimming invariant manifolds” (SwIMs) that act as one-way barriers that impede the motion of active tracers in the flow. For the hyperbolic flows, we investigate the structure of the barriers as a function of the imposed flow magnitude. For the vortex flow, we investigate the effects of SwIMs that encircle the vortex centers. We also test predictions of chaotic trajectories of smooth-swimming tracers for time-independent, two-dimensional flows.

8:26AM C32.00003 Towards the rheology of a concentrated array of spherical squirrmers, TIM PEDLEY, University of Cambridge, TAKUJI ISHIKAWA, Tohoku University, DOUGLAS BRUMLEY, University of Cambridge — Continuum models of dilute suspensions of swimming micro-organisms are well established and can incorporate external (gravitational) forces and torques as well as the particle stress generated by the swimming activity [1]. In a semi-dilute suspension of steady spherical squirrmers, hydrodynamic and steric interactions between cells can be computed in a pairwise manner, and Stokesian Dynamics (SD) has been developed for higher concentrations. The stress response to externally applied simple shear has been computed for semi-dilute suspensions [2]. Recently we have examined the stability of a concentrated planar array of identical bottom-heavy squirrmers, accounting for cell-cell interactions by the use of lubrication theory [3]. Here we seek to extend this theory to externally driven simple shear, in order to represent the macroscopic shear stress and normal stresses as functions of the shear-rate, the orientation of the applied shear to gravity, and the dimensionless parameters of the squirrmers in motion. Preliminary results are compared with those of a full SD computation. References: [1] Pedley, T.J. & Kessler, J.O. (1992) Ann. Rev. Fluid Mech. 24:313-358. [2] Ishikawa, T. & Pedley, T.J. 9:05AM C32.00006 Swimming near Tensorial Slip Surfaces, CHRISTOPHER DUPRE, SAVERIO SPAGNOLIE, University of Wisconsin-Madison — Surfaces with anisotropic mobilities present an intriguing opportunity for passively influencing the motion of microorganisms or active particles in their presence. We study the self-propulsion of a classical model of microorganism locomotion, Taylor’s swimming sheet, in the presence of one or two tensorial-slip surfaces. The swimming speed generally includes a lateral motion relative to the direction of undulatory waves on the body, and body rotation, and depends critically upon the distance to the wall(s). The theory also speaks to swimming and crawling near surfaces with rough boundaries.

9:18AM C32.00007 Upstream swimming of active Brownian particles in pressure-driven flow, ZHIWEI PENG, JOHN BRADY, California Institute of Technology — Active Brownian particles (ABPs) accumulate at boundaries that confine them owing to their persistent self-propulsion. In the presence of a pressure-driven flow, the fluid vorticity tends to rotate ABPs toward the upstream direction. As a result, ABPs in pressure-driven flow can exhibit a net upstream motion. In this work, we use continuum theory and Brownian dynamics simulation to study the effects of pressure-driven flow on the dynamics of ABPs. In particular, we quantify the net mean speed of ABPs in a channel, which results from a competition between downstream fluid advection and upstream swimming. We characterize the transition between net upstream and downstream motion as a function of the flow speed, Brownian diffusion and the intrinsic swimming speed of ABPs. Our results show that the interplay between self-propulsion, fluid vorticity and confinement provides a robust mechanism for upstream motility.

This work is supported by NSF Grant CBET 1803662.
and unviscid flow, and intermittent viscosity, GIUSEPPE NEGRO, LIVIO NICOLA CARENZA, Dipartimento di Fisica, Università degli Studi di Bari and INFN, Sezione di Bari, via Amendola 173, Bari, I-70126, Italy, ANTONIO LAMURA, Istituto Applicazioni Calcolo, CNR, Via Amendola 122/D, I-70126 Bari, Italy, GIUSEPPE CONNELLA, Dipartimento di Fisica, Università degli Studi di Bari and INFN, Sezione di Bari, via Amendola 173, Bari, I-70126, Italy., ADRIANO TIRIBOCCHI, Center for Life Nano ScienceLa Sapienza, Istituto Italiano di Tecnologia, 00161 Rome, Italy — Active fluids are systems where active components present in the fluid (microtubules with molecular motors such as kinesin or actomyosin bundles) display interesting collective ordering properties. Active fluids also exhibit peculiar rheological properties. Depending on the characteristic of the active stress, activity is capable to heighten viscosity, enough to develop shear-thickening properties in contractile systems or induce in extensile suspensions a superfluid regime under suitable condition. We study, by lattice Boltzmann methods, the rheological behavior of an emulsion made of an active polar component and an isotropic passive fluid. Different flow regimes are found by varying the values of shear rate and extensile activity (occurring, e.g., in microtubule-motor suspensions). By increasing activity, a first transition occurs from linear flow regime to spontaneous persistent unidirectional macro-scale flow, followed by another transition either to (low shear) intermittent flow regime with coexistence of states with positive, negative, and vanishing apparent viscosity, or to (high shear) symmetric shear thinning regime.

Generalized rheotaxis of active particles in confined Stokes flow, WILLIAM USPAL, University of Hawai'i at Manoa, Dept. of Mechanical Engineering — We consider spherical active particles exposed to shear flow near a planar surface. The swimming activity of a particle gives rise to interactions (e.g., hydrodynamic or chemical interactions) with the surface that couple back to the motion of the particle. Via a dynamical systems approach, we show that a robust directional response can emerge from the interplay of external flow and near-surface swimming activity. For instance, depending on the external flow strength and the character of the swimming activity of the particle, the particle can align against the flow direction (upstream rheotaxis) or nearly perpendicular to it (cross-stream rheotaxis). As an instructive and analytically tractable example, we apply our findings to the squirmer model of a mechanically actuated microswimmer. Using far-field approximations, lubrication theory, and exact numerical calculations, we identify the conditions on the squirming mode amplitudes to obtain the various steady states. Finally, we discuss collective rheotaxis of a group of squirmers. Overall, our findings demonstrate that microswimmers can exhibit surprisingly rich behavior when operating in confined flows, which occur in many of their envisioned applications.

Spatiotemporal Control of an Extensile Active Nematic Suspension1, MICHAEL NORTON, MICHAEL HAGAN, SETH FRADEN, Brandeis University — Active nematic suspensions are self-driven fluids that exhibit rich spatiotemporal dynamics characterized by director field buckling, defect nucleation/annihilation and chaotic trajectories of those defects. Towards developing experimental methods for controlling these dynamics, we consider an optimal control problem which seeks to find the spatiotemporal pattern of active stress strength required to drive the system towards a desired director field configuration. As an exemplar, we consider an extensile active nematic fluid confined to a disk which, in the absence of control, produces two topological defects that perpetually circulate, and seek the time-varying active stress field that drives the system to circulate in the opposite direction.

Feedback control of Marangoni instability in a thin film1, ANNA SAMOLOVA, ALEXANDER NEMPOMYASHCHY, Technion - Israel Institute of Technology — We use the feedback control for the suppression of Marangoni instability in a thin film heated from below. Our keen interest is focused on the oscillatory mode that was recently revealed in the case of the thermally insulated substrate. We apply the lubrication approximation to derive nonlinear amplitude equations which govern the coupled evolution of the layer thickness and the characteristic temperature. To stabilize the no-motion state of the film we apply the linear feedback control. The principle of such control is that we feed the information about instability back into the dynamics by changing the heat flux through the substrate that can affect the instability. Linear analysis shows that the control of the temperature deviation at the deformable free surface stabilizes the thin film heated from below effectively. To render the subcritical instability supercritical we apply the quadratic feedback control. The weakly nonlinear analysis of the amplitude equations is provided for two types of regime: a pair of the travelling waves and a pair of the standing waves. The conditions of stable supercritical solutions are obtained for both types of regime.

Linear stability analysis of plane Poiseuille-Couette flow over a permeable surface1, SAMAN HOOSHYAR, PARISA MIRBOD, University of Illinois at Chicago — The instability of plane Poiseuille-Couette flow (PCF) over a porous medium has been studied extensively due to its wide range of applications in environmental engineering, oil and pharmaceutical industries, and geophysical problems. This study investigates the effect of imposing Couette to the instability of plane Poiseuille flow over a porous surface. We performed linear stability analysis to analyze the impact of upper moving wall on the porous media with different geometrical parameters and to obtain the most unstable perturbation modes. The Navier-Stokes and Brinkman equations are coupled to characterize the behavior of the fluid and porous layers, respectively. It was found that the presence of Couette flow always destabilizes the Poiseuille flow when the velocity of the upper moving wall is smaller than the cutoff velocity, defined as the velocity at which the flow stabilizes and it is a function of the depth ratio and porous resistivity. The flow becomes more stable as the wall velocity exceeds the cutoff velocity. Also, increasing the wall velocity results in an instability mode shift from the fluid layer mode to the porous layer mode.

in the case of a pre-coated glass, the famous “wine tears” emerge from a reverse undercompressive shock originating at the meniscus. We observe both compressive and undercompressive waves in new experiments and we argue that, and the behavior of the meniscus. In the lubrication limit we obtain an equation that is already well-known for rising films in the presence of inertia. The nonlocal effect of the electric field solution in particular is examined in detail.

Via comparison with Direct Numerical Simulations, we show that good accuracy can be maintained even for thick films at moderate levels of inertia. The nonlocal effect of the electric field solution in particular is examined in detail.

8:39AM C33.00004 Electrostatic control of instabilities in thick liquid layers, ALEXANDER WRAY, University of Strathclyde, RADU CIMPEANU, University of Oxford — We apply a recently developed method for modelling thick flows (Wray et al., 2017) to the Moffatt problem for flow on the outside of a rotating cylinder, and the control thereof using electric fields. Via comparison with Direct Numerical Simulations, we show that good accuracy can be maintained even for thick films at moderate levels of inertia. The nonlocal effect of the electric field solution in particular is examined in detail.

8:52AM C33.00005 Low-order modelling of non-axisymmetric flow on the exterior of a fibre1, JAMES REILLY, ALEXANDER WRAY, STEPHEN WILSON, Strathclyde University, OMAR MATAR, Imperial College London — Flows on the outside of fibres have received extensive attention over the years. Even in the Stokes limit they exhibit interesting behaviour due to dual role of capillarity, exhibiting simultaneously both a destabilising “hoop stress” in the azimuthal direction as well as a more conventional stabilising effect in the axial direction. In this limit, the flow is always axisymmetric. However, for sufficiently thick films and with a sufficiently high Reynolds number, non-axisymmetric instabilities are observed. While this has been predicted using linear stability theory and confirmed using direct numerical simulations and experimentation, it has proven problematic to model. Existing models have either required that films be both thin and close to threshold (Shiang and Sivashinsky, 1982) or that the flow be axisymmetric (Ruyer-Quil et al., 2008). Using the methodology of Wray et al., 2017, we develop a fully nonlinear model for thick flow down the outside of a fibre at moderate levels of inertia. We compare its predictions against those from numerical computations in both the linear and nonlinear regimes to assess its validity, before using it to elucidate the complex interplay of viscosity, capillary, inertia, and gravity that gives rise to the observed flow patterns.

9:05AM C33.00006 Nonlinear evolution of a dewetting bilayer thin film on a soft-gel layer, PUSHPAVANAM SUBRAMANIAM, DINESH BHAGAVATULA, Indian Institute of Technology Madras — The nonlinear evolution of dewetting bilayer thin film on a soft-gel is investigated in this work. The fluids are considered to be Newtonian and the soft-gel-layer is modelled as a linear viscoelastic solid. The free surface of the top fluid is exposed to air. The van der Waals attractive forces between the soft-gel layer and the fluids are the primary driving forces responsible for breaking of the thin films. Short range repulsive forces play a key role in the dynamics of the system for very thin bilayers. The nonlinear evolution equations for this system are derived using a lubrication approximation. Linear stability analysis of the system confirms two long wave instabilities one at the liquid-liquid interface and other at the free surface arise in the system. The liquid-liquid instability is dominant when the attractive forces between the soft-gel-layer and the bottom fluid are strong. For a range of parameters both instabilities coexist in the system. The short range repulsive forces can suppress both these instabilities. The soft-gel layer has a destabilizing effect on the long wave instabilities.

9:18AM C33.00007 Asymptotics regimes in elastohydrodynamic and stochastic levelling on a viscous film1, CHRISTIAN PEDERSEN, Department of Mathematics, University of Oslo, Oslo, Norway, JOHN NIVEN, Department of Physics and Astronomy, McMaster University, Hamilton, Ontario, Canada, THOMAS SALEZ, University of Bordeaux, CNRS, LOMA, Talence, France, KARI DALNOKI-VERESS, Department of Physics and Astronomy, McMaster University, Hamilton, Ontario, Canada, ANDREAS CARLSON, Department of Mathematics, University of Oslo, Oslo, Norway — We study the relaxation dynamics of an elastic plate resting on a thin viscous film that is supported by a solid substrate. By combining scaling analysis, numerical simulations and experiments, we identify asymptotic regimes for the elastohydrodynamic leveling of a surface perturbation when the flow is driven by either elastic bending of the plate or thermal fluctuations. In both cases we identify two distinct regimes when the perturbation height is either much larger or much smaller than the thickness of the pre-wetted viscous film. Our analysis reveals a distinct crossover between the similarity exponents with the ratio of the perturbation height to the film height.

9:31AM C33.00008 A theory for undercompressive shocks in tears of wine1, HANGJIE JI, YONATHAN DUKLER, CLAUDIA FALCON, ANDREA BERTOZZI, Department of Mathematics, University of California, Los Angeles — We revisit the tears of wine problem for thin films in water-ethanol mixtures and present a new model for the climbing dynamics. The new formulation includes a Marangoni stress balanced by both the normal and tangential components of gravity as well as surface tension which lead to distinctly different behavior. The prior literature did not address the wine tears but rather the behavior of the film at earlier stages and the behavior of the meniscus. In the lubrication limit we obtain an equation that is already well-known for rising films in the presence of thermal gradients. Such models can exhibit non-classical shocks that are undercompressive. We present basic theory that allows one to identify the signature of an undercompressive wave. We observe both compressive and undercompressive waves in new experiments and we argue that, in the case of a pre-coated glass, the famous “wine tears” emerge from a reverse undercompressive shock originating at the meniscus.

9:44AM C33.00009 Dewetting through Forests of Micropillars. YU QIU, KE XU, Massachusetts Institute of Technology, AMIR PAHLAVAN, Princeton University, RUBEN JUANES, Massachusetts Institute of Technology — When a low-viscosity nonwetting fluid displaces a higher-viscosity wetting liquid in a rough surface consisting of a forest of micropillars, a film of the viscous defending fluid is left behind the advancing fluid-fluid front. Here, we investigate experimentally the dewetting of this residual film, and we contrast it with the dewetting that occurs on a smooth surface. We find that there are three regimes: “no film” at low capillary number; “thick film” at sufficiently high capillary number, and a novel “thin film” regime at intermediate capillary number. In this latter regime, the dewetting occurs as the residual viscous fluid retracts as a film of uniform thickness through (and not over) the micropillars. We propose necessary geometric conditions for the emergence of this new dewetting dynamics, and delineate the different dewetting regimes on a phase diagram, which quantitatively matches lab experiments conducted on a microstructured Hele-Shaw cells. The long-term state of the system induced by dewetting is a pattern of residual film clusters confined in the micropillar forest—a fluid arrangement that impacts macroscopic hydrodynamics and heat transfer efficiency.

9:57AM C33.00010 Deformation and dewetting of liquid films under gas jets. CHINASA OJIAKO, Loughborough University, RADU CIMPEANU, Oxford University, HEMÁKA BANDULASENA, ROGER SMITH, DMITRI TSHELUIKO, Loughborough University — We study the deformation and dewetting of a liquid film in a cylindrical beaker under the influence of an impinging gas jet. To obtain initial insight into relevant regimes and timescales of the system, we first derive a reduced-order model (a thin-film equation) based on the long-wave assumption and on appropriate decoupling the gas problem from that for the liquid [1-3] and taking into account a disjoining pressure [4]. We also perform direct numerical simulations (DNS) of the full governing equations using two different approaches, the Computational Fluid Dynamics (CFD) package in COMSOL and the volume-of-fluid Gerris package. The DNS are used to validate the results for the thin-film equation and also to investigate the regimes that are beyond the range of validity of this equation. We additionally compare the computational results with experiments and find good agreement.

Sunday, November 24, 2019 8:00AM - 10:10AM – Session C34 Flow Instability: Rayleigh-Taylor | 616 - Irmgard Bischofberger, MIT

8:00AM C34.00001 Pattern formation of a thin film flowing under an inclined plane1. PIER GIUSEPPE LEDDA, GAETAN LERISSON, GIOELE BALESTRA, FRANCOIS GALLAIRE, Laboratory of Fluid Mechanics and Instabilities, Ecole Polytechnique Federale de Lausanne, CH-1015 Lausanne, Switzerland — We discuss the pattern formation of a thin film flowing under an inclined planar substrate, combine theoretical, experimental and numerical results. The phenomenon is related to the Rayleigh-Taylor instability, in which one heavier fluid is placed above a lighter one. When an upper wall and the substrate inclination are considered, a variety of patterns are observed. The natural and forced dynamics of the flat film to spanwise perturbations and the resulting non-linear structures are studied; in both cases, spanwise-periodic, streamwise-aligned structures, called rivulets, arise. The impulse response of a flat film is numerically and experimentally studied. We analyze the linear response, which does not show any preferential direction; a weakly non-linear model highlights however the selection of the streamwise structures. The fully non-linear evolution leads to a steady pattern characterized by fully saturated rivulets, the profile of which is analyzed in detail. A secondary stability analysis reveals the presence of a range of parameters in which only rivulets are observed, in agreement with the experimental observations. Outside of this range, lenses appear on the rivulets, which may eventually drip.

8:13AM C34.00002 A Buoyancy–Shear–Drag-Based Turbulence Model for Rayleigh–Taylor, Reshocked Richtmyer–Meshkov, and Kelvin–Helmholtz Mixing1. OLEG SCHILLING, Lawrence Livermore National Laboratory — A phenomenological turbulence model for Rayleigh–Taylor, reshocked Richtmyer–Meshkov, and Kelvin–Helmholtz instability-induced mixing is developed using a general buoyancy/shear/drag model. Analytical solutions are used to calibrate the coefficients to predict specific values of the mixing growth parameters and exponents. The model is applied to the three instability cases to demonstrate its utility. It is shown that the numerical solutions of the model calibrated using specific values of the instability growth parameters and exponents: (1) produces mixing layer widths in agreement with the expected self-similar growth power laws; (2) gives spatiotemporal profiles of turbulent fields that are expected and consistent with previous results; (3) predicts the expected power-law growths and decays of the spatially-integrated turbulent fields, and; (4) gives spatiotemporal profiles of the mean fields that are expected and consistent with previous results.

8:26AM C34.00003 Combined effects of finite plate thickness and acceleration rates on Rayleigh-Taylor instability in elastic-plastic materials. ARINDAM BANERJEE, RINOSH POLAVARAPU, AREN BOYACI, Lehigh University — Majority of theoretical and computational studies of Rayleigh-Taylor instability (RTI) in solid-fluid interfaces assume the materials to be incompressible with infinite/semi-infinite thickness subjected to a constant driving acceleration. A recent theoretical study by Piriz et al. (PRE textbf{95}, 053108, 2017) has explored finite thickness effects using an impulsive acceleration profile where the initial rate of increase in the driving pressure is nearly infinite. In previous studies, our group has addressed the independent effects of the finite plate/slab thickness and finite rate of increase in driving acceleration (pressure). In this talk, we will address the combined effects of both the aforementioned parameters on RTI by employing the soft solid (mayonnaise)-air interface using our rotating wheel experimental setup. A set of experiments was run at four different acceleration rates in combination with three test-section container halves of varying depths using initial conditions with different wavelengths and amplitudes. The aggregate effects of these parameters on interface growth were quantified in terms of instability acceleration, which signifies the material transition from elastic-plastic regime to the viscous regime. In addition, the growth rates for each experiment are determined and compared to the existing theoretical models which tackle the RTI problem in solids.

8:39AM C34.00004 Suppression of the Rayleigh-Taylor instability in a confined geometry

We study the Rayleigh-Taylor instability of two miscible fluids in a Hele-Shaw geometry; confined in a thin gap, of size \( b \), between two large flat plates. Using this geometry, we inject a fluid into another with a different density as to produce an unstable situation in which a heavy fluid initially resides above a layer of lighter fluid. Below a critical gap spacing, \( b_c \), we find that no Rayleigh-Taylor fingers form despite the fluid density gradient that typically instigates the instability. We use simulations, validated by comparison with experiments, to determine \( b_c \) as a function of the difference in densities \( \Delta \rho \), the viscosities \( \eta \), and diffusivities \( D \). We argue that this critical confinement scale is set by a competition between destabilizing buoyancy forces and stabilizing effects of viscosity and diffusion. An argument based on dimensional analysis gives scaling exponents consistent with the observed results, \( b_c \sim (D\eta/g\Delta \rho)^{1/3} \). In addition to the critical gap, we measure the characteristic wavelength and onset time in this confined geometry and compare it to the theoretical predictions for the Rayleigh-Taylor instability in open space.

8:52AM C34.00005 Group theory analysis of early-time scale-dependent dynamics of the Rayleigh-Taylor instability with time varying acceleration

We consider the long-standing problem of Rayleigh-Taylor instability with variable acceleration, and focus on the early-time scale-dependent dynamics of an interface separating incompressible ideal fluids of different densities subject to a power-law function of time for a spatially extended three-dimensional flow periodic in the plane normal to the acceleration. By employing group theory analysis, we discover two distinct sub-regimes of the early-time dynamics depending on the exponent of the acceleration power-law. The time scale and the early-time dynamics are set by the acceleration for exponents greater than \(-2\), and by the initial growth-rate (due to, e.g., initial conditions) for exponents smaller than \(-2\). At the exponent value \(-2\) a transition occurs from one sub-regime to the other with varying acceleration strength. For a broadband range of acceleration parameters, the instability growth rate is explicitly found, the dependence of the dynamics on the initial conditions is investigated, and theory benchmarks are elaborated.

9:05AM C34.00006 Rayleigh-Taylor Instability Between Unequally Stratified Layers

We consider the classical Rayleigh-Taylor instability between two otherwise stably stratified layers that a new growth is limited by the stratification and can be arrested before the instability reaches the boundaries. Here we study the intermediate case where one of the two layers is stably stratified and the other homogeneous, thus introducing an asymmetry where the instability grows into one layer without restriction, but is eventually arrested by the stratification in the other layer. Experimental measurements of the density and velocity fields show both similarities and differences compared with both the limiting cases in terms of both the evolution of the height of the mixing zone and the final stratification achieved.

9:18AM C34.00007 Optimal perturbations for linear stability of two fluid columns of different densities subject to gravity

We study the linear stability of a vertical interface separating two fluid columns of different densities under the influence of gravity. Initially, we assume quasi-steady state (QSSA) of the base flow and pose the problem as an eigenvalue problem. This result in an initial condition that leads to the maximum growth of disturbances at a finite time. Preliminary results indicate that the perturbation energy of wave modes with small wave numbers may experience substantial transient growth prior to decaying asymptotically in time, despite the assumption of the linearized problem. It is also found that the maximum growth is achieved for an order of magnitude higher than that of the non-optimized case. The sensitivity of perturbation growth with respect to initial time, density, and viscosity ratios will be investigated.

9:31AM C34.00008 Experimental investigation of Rayleigh—Taylor mixing in gases using simultaneous PIV-PLIF

Particle image velocimetry (PIV) and planar laser induced fluorescence (PLIF) — are employed to obtain mixing width and simultaneous velocity-density data. PLIF using acetone is implemented for the first time for convective-type (flowing) statistically stationary RT experiments with gases. Velocity and density statistics, and their correlations (\( u', v', \rho', \rho' v' \)) are presented. As Atwood number for current experiments exceeds the widely accepted \( A = 0.1 \) limit for Boussinesq approximation, non-Boussinesq effects and anisotropy effects at this Atwood number are evaluated using metrics like higher-order moments (skewness, kurtosis) and anisotropy tensor. Results from current experiments are compared with existing turbulent RT mixing models (like BHR models). Reference: AKULA, B. & RANJAN, D. 2016 Dynamics of buoyancy-driven flows at moderately high Atwood numbers. Journal of Fluid Mechanics 795, 313–355.

9:44AM C34.00009 The adjoint Rayleigh criterion in compressible reacting flow instabilities

Thermoacoustic oscillations are one of the most challenging flow instabilities faced by the gas turbine and rocket motor industry. The instability mechanism is described in the time domain by the Rayleigh criterion. In this contribution, the Rayleigh criterion is interpreted in the frequency domain by deriving functional formulae for the eigenvalue. The first variation of the Rayleigh criterion is calculated both in the time and frequency domain, both with and without Lagrange multipliers (adjoint variables). The Lagrange multipliers are physically interpreted with the system's observables, e.g., pressure, velocity, temperature. Finally, the adjoint Rayleigh criterion is proposed. The relations and criteria proposed can enable the calculation of adjoint sensitivities from measurable quantities in experiments. The methodology proposed is versatile and can be applied to other problems in flow instability that are tackled by adjoint analysis.

Sunday, November 24, 2019 8:00AM - 10:10AM – Locomotion 617 - Bhargav Rallabandi, University of California, Riverside

8:00AM C35.00001 How to catch a microswimmer. IVAN TANASJIEVIC, ERIC LAUGA, University of Cambridge — An active particle swimming in a flow undergoing solid-body rotation always ends up diverging away from the centre of rotation. Is it possible to design a Stokes flow vortex that would trap an active particle? We address mathematically the fate of swimmers modelled as spheres, or prolate swimmers, swimming with prescribed velocities in a number of elementary vortical flows in 2D and 3D. We predict theoretically the existence of bounded orbits, which are confirmed by numerical simulations. We also address the role of fluctuations for the swimmer. These results open the possibility of designing microswimmer traps, thereby facilitating biophysical studies of cell motility.

8:13AM C35.00002 Self-propulsion of chemically active colloids. BHARGAV RALLABANDI, University of California, Riverside, FAN YANG, HOWARD STONE, Princeton University — Phoretic particles are able to propel in the presence of externally applied or self-generated chemical gradients. Focusing on the non-Brownian limit, we discuss the autonomous motion of colloids that generate chemical gradients through surface reactions and consequently self-propel via diffusiophoresis. We develop a general framework by combining truncated multipole expansions for the hydrodynamic and chemical fields with the Lorentz reciprocal theorem. Applying the framework to particles with uniform surface chemical fluxes, we find that the particles translate primarily through chemical interactions, whereas hydrodynamic interactions are typically subdominant. We discuss the utility of truncated expansions in accurately describing particle trajectories, while also contrasting autophoretic motions in ionic and non-ionic solvents. We apply the model to a mixture of two particle populations and find behaviors that include pair-chasing, attraction and cluster formation.

8:26AM C35.00003 Propulsion of spherical microparticles through spontaneous symmetry breaking in mucus. HENRY FU, University of Utah, LOUIS ROGOWSKI, Southern Methodist University, JAMEL ALI, Florida Agricultural and Mechanical University-Florida State University, XIAO ZHANG, MINJUN KIM, Southern Methodist University — Symmetries have long been used to understand when propulsion is possible in microscale systems. For biological force- and torque-free swimmers the Scallop theorem applies kinematic reversibility of Stokes flow has been to understand which swimming strokes are asymmetric under time-reversal and capable of propulsion. Currently, artificially propelled magnetic micro- and nanoparticles are being utilized in a variety of techniques including hyperthermia, drug delivery, and magnetic resonance imaging. Rotation of rigid magnetic particles by an external magnetic field are a promising category of such artificial propulsion. So far it has been expected that spherical beads are too symmetric to be propelled in this fashion, but here we present experiments demonstrating that rotating spherical magnetic beads in a solution of mucin seem to display a spontaneous symmetry-breaking propulsion. We perform a perturbative analysis of a rotating sphere in a nonlinear polymeric fluid that elucidates the physical mechanism behind such a symmetry breaking.

8:39AM C35.00004 Locomotion of a rotating cylinder pair with periodic gaits at low Reynolds numbers. LINGBO JI, WIM M. VAN REES, Massachusetts Institute of Technology — We investigate the effect of periodic gaits on the self-propulsion of two side-by-side rotating cylinders at low Reynolds numbers. This cylinder-pair model serves as a prototype for engineered micro-swimmers due to its simple design and operation. To study periodic gaits, we impose a zero-net-rotation constraint on each cylinder for each swimming cycle. By numerically solving the Stokes flow around the cylinders, we can identify the optimal rotation patterns that enable the cylinder pair to travel the largest distance for a range of energy budgets. We extend this study to three dimensions by investigating the optimal swimming strategies for pairs of spheroids within a range of aspect ratios, and compare their performance to traditional Purcell swimmers and other locomotion strategies at low Reynolds numbers.

8:52AM C35.00005 Microswimmer and obstacle interactions mediated by pressure fields. FLORENCIO BALBOA USABIAGA, Flatiron Institute, QUENTIN BROSSEAU, Courant Institute, New York University, ENKELEIDA LUSHI, New Jersey Institute of Technology, YANG WU, New York University, LEIF RISTROPH, Courant Institute, New York University, JUN ZHANG, MICHAEL WARD, New York University, MICHAEL J. SHELLEY, Flatiron Institute — We revisit the problem of microswimmer orientation near boundaries. We will show how elongated swimmers create high and low pressure nodes around them and how these pressure nodes are enough to tilt the swimmers around obstacles. We address this problem with a combination of theory, simulations and experiments. We use the Rigid multiblob method to model phoretic swimmers near walls and compare the predictions with experiments of bimetallic micro-rods swimming in hydrogen peroxide solutions. Finally, we will use our mechanical explanation to suggest how phoretic swimmers can be designed to have preferred hydrodynamic interactions with walls.

This work was supported by NSF-MRSEC program DMR-1420073, and NSF Grants DMS-1463962 and DMS-1620331.
9:05AM C35.00006 Hydrodynamics of Microswimmers Trapped at Fluid-Fluid Interfaces, NICHOLAS CHISHOLM, KATHLEEN STEBE, University of Pennsylvania — Microswimmers on or near fluid interfaces have pronounced changes in their motion, in their interactions with neighboring colloids, and in their collective behaviors. These motions and interactions can be harnessed to direct colloidal assembly or alter interfacial transport conditions. However, the manner in which a fluid interface alters microswimmer motion is not yet understood. To address this gap, we develop a flow singularity model to identify leading order modes for active colloids on interfaces in the limit of small Reynolds and capillary numbers. We discuss a “clean” interface in which there is no jump in tangential stresses at the interface. We also consider an incompressible interface, as is typical for colloids on interfaces in the presence of surfactant. Thereafter, we examine interactions between a microswimmer and passive “tracer” particles for two microswimmer trajectory types: swimming in a straight line or in circular paths. These results will be useful in future work on the use of active colloids to direct and enhance transport at interfaces.

9:18AM C35.00007 Active Particles Powered by Quincke Rotation in a Bulk Fluid, DEBASHIS DAS, ERIC LAUGA, Department of Applied Mathematics and Theoretical Physics, University of Cambridge — How are groups of living organisms such as flocks of birds, sheep, schools of fish and bacterial colonies able to self-organize and display collective motion? This question has fascinated scientists for decades and has given rise to the new field of ‘active matter’. One of the key features of active matter is that it is composed of self-propelled units that move by consuming energy from their surrounding with a direction of self-propulsion typically set by their own anisotropy (shape or function) rather than by an external field. In this work, we show how an electrohydrodynamic instability called Quincke rotation can be exploited to develop an ideal self-propelled particle in a bulk fluid. Dielectric particles suspended in a weakly conducting fluid are known to spontaneously start rotating under the action of a sufficiently strong uniform DC electric field due to Quincke rotation. This rotation can be converted into translation when the particles are placed near a surface providing useful model systems for active matter. Using a combination of numerical simulations and theoretical models, we demonstrate that it is possible to convert the spontaneous Quincke rotation into spontaneous translation even in the absence of surfaces by relying on geometrical asymmetry instead.

9:31AM C35.00008 Harnessing low Reynolds number flow for net migration: Locomotion of a deformable microcapsule by random fluid forces, TAKUJI ISHIKAWA, TAKERU MORITA, TOSHIHiro OMORI,YOHEI NAKAYAMA,SHOICHI TOYABE,Tohoku University — Random noise in low Reynolds number flow has rarely been used to obtain net migration of microscale objects. In this paper, we show that net migration of a microscale object can be extracted from random directionnal fluid forces, by introducing deformability and inhomogeneous density into the object. As a model system, we considered an elastic microcapsule containing fluid and a rigid sphere with different densities. The numerical results showed that the microcapsule could migrate vertically downward when random forces were applied using a migration mechanism based on non-reciprocal body deformation in Stokes flow. We also developed a mathematical framework to describe the deformation-induced migration caused by noise. The proposed theory showed good agreement with the simulation results, and illustrated that drag asymmetry acts like a ratchet to generate net downward motion under noise. These results provide a basis for understanding the noise-induced migration of a micro-swimmer and are useful for harnessing energy from low Reynolds number flow.

1 JSPS KAKENHI Grant No. 17H00853

9:44AM C35.00009 Generalised geometric swimming for Stokes flow, LYndon KOENS, Macquarie University, ERIC LAUGA, University of Cambridge — Shapere and Wilczek first demonstrated that the displacement of a microscopic swimmer was related to path integrals over a gauge field. This field is a function of the swimmer’s configuration and laboratory frame position. For simple 1D swimmers, Stokes theorem can be used to relate the net displacement from a stroke to the area within a curve. This provides an effective method to determine the optimal strokes for displacement. However, a similar visualization is difficult for many swimmers because of complex configuration spaces or non-commuting variables. In this talk I will use a Purcell swimmer to demonstrate how to overcome these issues. These techniques reveal general properties about the displacement of microswimmers while offering a new method to optimise them.

9:57AM C35.00010 Magnetocapillary Swimmers: a Self-Assembled System to Study Locomotion, Transport Cargoes and Mix Fluids, GALIEN GROSJEAN, YLONA COLLARD, University of Liege (ULiege), MAXIME HUBERT, ULiège / Friedrich-Alexander University (FAU), ALEXANDER SUKHOV, Helmholtz Institute Erlangen-Nuremberg (HI-ERN), JENS HARTING, HI-ERN / Eindhoven University of Technology, ANA-SUNCANA SMITH, FAU / Institute Ruder Boskovic, NICOLAS VANDEWALLE, ULiège — Because of capillary forces, small objects floating on a liquid tend to aggregate. Combined with the induced rotation from a magnetic field, this effect can be used to assemble soft-ferromagnetic spheres into tunable structures. When they are exposed to oscillating magnetic fields, these assemblies spontaneously move along the interface. This is due to a breaking of time-reversal symmetry in their adopted shapes. These structures are conceptually simple, chemically inert, and spontaneously form without direct intervention or complex microfabrication process. Therefore, they offer a very wide range of possibilities, from the experimental study of the basic physical principles of locomotion, to the development of complex tasks such as cargo transport and fluid mixing.

Session C36 Electokinetic Flows: Induced Charge Flows and Instabilities 618 - Igor Novoselov, University of Washington

8:13AM C36.00002 Asymmetric Rectified Electric Fields Generate Flows that can Dominate Induced-Charge Electrokinetics, S. M. H. HASHEMI AMREI, GREGORY MILLER, WILLIAM RISTENPART, University of California Davis — We derive a generalized induced-charge electrokinetic (ICEK) velocity around a conducting object placed in an arbitrary multimodal electric field. The generalized model allows consideration of asymmetric rectified electric fields (AREFs), which have recently been established to occur in liquids where the ions present have unequal mobilities. Including the AREF yields fluid velocities in which both the direction and the magnitude depend sensitively on the applied potential, frequency, ionic type and strength, and even the exact placement of the object between parallel electrodes. The results provide a new explanation for the long-standing question of flow reversals observed in ICEK systems.

8:26AM C36.00003 Electric-Field Induced Pattern Formation in Layers of DNA Molecules at the Interface between Two Immiscible Liquids1, JOHANNES HARTMANN, STEFFEN HARDT, SICHENG ZHAO, Institute for Nano- and Microfluidics, Technische Universität Darmstadt, ADITYA BANDOPADHYAY, Department of Mechanical Engineering, India Institute of Technology Kharagpur — Electrohydrodynamic/electrokinetic flows play a key role as driving mechanism of pattern formation in colloidal dispersions and at liquid-liquid and liquid-solid interfaces with adsorbed particles. We report an analogous phenomenon of electric field-induced concentration patterns of DNA molecules at the interface of an aqueous two-phase system. The electric field, applied normal to the liquid-liquid interface, drives the molecules to the interface where they get trapped. Hydrodynamic interactions between the molecules arise by electroosmotic flow due to the Debye layer around the polyelectrolytes, leading to pattern formation in the DNA concentration field at the interface. We describe the time evolution of the concentration field by a non-linear integro-differential equation. A linear stability analysis of the equation yields a critical time after which the system destabilizes if exited by a mode of given wavelength. We find that the scaling behavior predicted by theory agrees with experimental results. The presented scheme could be used as an efficient method to pre-concentrate DNA molecules at an interface.

8:39AM C36.00004 Enhanced Ion Transport by Controlling Electroconvective on Ion Exchange Membranes with Patterned Structures1, JOONHYEON KIM, SANGHA KIM, RHOKYUN KWAK, Hanyang University, Korea — Patterned structure in fluid systems has been used to generate vortices, enhancing mass transfer. Here, we investigate new role of this vortex promoter, i.e. controlling an electrically driven hydrodynamic instability (i.e., a.k.a electroconvection (EC)) on ion exchange membranes. The patterned structures not only generates vortices as a vortex promoter, but also acts as a shelter to keeping EC from being suppressed by shear flow. To verify these effects, we visualized EC over six different patterns under various applied voltages. The strength of EC was then quantified by visualizing velocity and vorticity fields. In current-voltage response, we found that i) conductive ion flux is inversely proportional to the occupied area of the pattern in Ohmic regime, ii) stronger vortex promotion with a larger vortex area induces a shorter or even negligible length of limiting regime, and iii) the area of sheltered EC benefiting from the pattern is directly proportional to the convective ion flux in overlimiting regime. Considering relationship between ion flux and roles of structures synthetically, isosceles triangle pattern shows the highest ion flux through the membrane as it is the best option for a conductor and the second best for the vortex promoter and EC shelter.

8:52AM C36.00005 Pattern formation of three-dimensional electroconvection on a charge selective surface1, SOOHYEON KANG, RHOKYUN KWAK, Hanyang University, Korea — Electroconvection (EC) has long been known for enhancing ion flux in various electrochemical systems, but its dynamics is yet to be probed in three-dimensions. In this paper, we describe the first laboratory observation of 3-D EC on an exchange membrane and its pattern diversification. Combining experiment and scaling analysis, we successfully categorized three distinguished patterns of 3-D EC according to Reynolds number (Re), electric Rayleigh number (RaE) and Schmidt number (Sc) as i) polygonal, ii) transverse, or iii) longitudinal rolls. If Re increases or RaE decreases, pure longitudinal vortices are presented. On the other hand, transverse rolls are formed between longitudinal rolls, and two rolls are transformed as polygonal rolls at higher RaE or lower Re. In this pattern selection scenario, Sc determines the critical electric Rayleigh number (RaE) for the onset of each transverse or polygonal rolls, resulting RaE∗ ∼ Re∗Sc. We also verify that convective ion flux by EC (represented by an electric Nusselt number, NuE) is fitted to a power law, NuE ∼ RaE0.48Sc−0.39. This work was supported by the Climate Change Response Technology Development Project (NRF-2017M1A2A2047475) and the Basic Research Project (NRF-2019R1C1C1008262) from the National Research Foundation of Korea.

9:05AM C36.00006 Numerical analysis of 2D and 3D electrohydrodynamic convection instability with crossflow1, YIFEI GUAN, JAMES RILEY, IGOR NOVOSSELOV, University of Washington — The study focuses on the electro-hydrodynamic (EHD) instability for flow between to parallel electrodes with unipolar charge injection with crossflow. Lattice Boltzmann Method (LBM) with two-relaxation time (TRT) model is used to study flow pattern [1]. Under strong charge injection and high electrical Rayleigh number, the system exhibits electroconvective vortices. Disturbed by different perturbation patterns, the flow patterns develop according to the most unstable modes. The unstable modes are obtained by dynamic mode decomposition (DMD) on the transient numerical solutions. Once the steady-state solution is obtained, Couette and Poiseuille cross-flow are applied. The flow patterns change according to the strength and direction of the cross-flow. When the cross-flow velocity is greater than a threshold value, in the 2D scenario, the vortices are suppressed [2], and in 3D the instability flow patterns would develop into streamwise rolling patterns. 9.18AM C36.00007 A Front Tracking Method for the Investigation of the Electrohydrodynamic Instability Between Two Immiscible Fluids, ILKE KAYKANAT, Bogazici University, METIN MURADOGLU, Koc University, KEREM UGIZ, Bogazici University — When an electric field is applied to the flat interface between two immiscible liquids flowing in a microchannel, the interface can be deflected and microdroplets can be obtained. In this study, a front-tracking method is presented for direct numerical simulations of two-phase systems to study the effects of the electric field applied normal to the flat interface between two immiscible, Newtonian fluids. The method is developed using a one-field formulation of the governing equations. The interface is tracked explicitly using a Lagrangian grid and the flow equations are solved on a fixed Eulerian grid. The effects of the applied voltage, the viscosity, and the base-flow strength on the nonlinear evolution of the interface are studied. Furthermore, in this study, the results obtained by the interface tracking method will be compared with the results obtained by both long-wave analysis and the experimental results obtained in our group.

9.31AM C36.00008 Electroconvection near a metal electrode surface, GAJOIN LI, LYNDEN ARCHER, DONALD KOCH, Cornell University — Electroconvection in electrodeposition leads to fast dendrite growth undermining the efficacy of the process. Above a critical voltage, the electrohydrodynamic instability generates an electro-osmotic slip velocity at the edge of the space charge layer, creating convective flows in the electrolyte which cause an overlimiting current and a nonuniform ion flux. The nonuniform deposition of cations on a metal anode and its coupling with the electroconvection cause fast dendrite growth and lead to premature cell failure. The deposition rate of cation on the metal surface, which is described by the well-known Butler-Volmer equation, determines the ion transport below the limiting current. However, how does it affect the electroconvection in the overlimiting regime is not clear yet. In this work, we use the stability analysis and direct numerical simulation to investigate the linear instability and the dynamics of the electroconvection.

9.44AM C36.00009 Surface Reaction Driven Flow, ABIMBOLA ASHAJU, JEFFERY WOOD, ROB LAMMERTINK, University of Twente — Bimetallic nanorods in form of microswimmers within an aqueous solution exhibits self-propulsion that is powered by self-electrophoresis. This bimetallic catalytic system can be immobilized to generate convective flow thereby acting as a micropump. In this work, we focus on experimental and numerical analysis that provides fundamental insight on the key elements including the generated electric field, reaction kinetics and diffusion-electroosmotic phenomena that control the resulting mass transport characteristics in these systems. The catalytic current between the electrodes and the induced potential that governs the reactive fluxes are measured electrochemically, proton concentration gradients originating from the catalytic reaction are imaged and quantified using fluorescence lifetime imaging, while the fluid flow is visualized with 3D particle tracking. Numerical simulations reveals the interplay of electrodes surface reactivity pattern represented by the dimensionless Damkohler number, with the electrokinetic phenomena that controls the release and depletion of protons and consequently the resulting induced fluid flow. This work highlights the ability of surface induced convective fluid flow in electrochemical systems to reduce mass transport limitations.

9.57AM C36.00010 Experimental and numerical determination of flow mixing enhancement in electrokinetics cross shaped microchannel flows due to spatially periodic wall perturbations, AMADOR GUZMAN, MARIO DICAPUA, DAMING CHEN, FRANCISCO MONTERO, MARIA CANALES, Pontificia Universidad Catolica de Chile, LABONACHIP TEAM — Liquid flows in microchannels usually occur at very low Reynolds numbers (<1) because inertial forces are strongly dumped by the very small microchannel characteristic length and the dominant viscous forces. When an electrical field is applied to the microchannel ends, a time-dependent stable flow arises at a very low Reynolds number because another non dimensional parameter, the Rayleigh number, takes a dominant role. When the Rayleigh numbers surpass a threshold value, a unstable behavior is obtained, the flow becomes chaotic and consequently leading to an increase of the fluid mixing that is particularly important when liquids with different electrical conductivities need to be mixed, particularly in physiological flows. One way of achieving this type of behavior but to a lower critical Rayleigh number is by adding spatially periodic inhomogeneities to the channel walls. In this research, we investigate the flow mixing enhancement occurring in a cross-shaped microchannels when liquids with different electrical conductivities flow through the microchannel at different inlets and flows downstream due to the application of an electrical field and get together in the outlet branch of the microchannel, which contain spatial periodic wall inhomogeneities. Experiments and numerical simulations are carried out to determine and evaluate stable and unstable behaviors and evaluate the flow mixing enhancement.

Sunday, November 24, 2019 8:00AM - 10:10AM
Session C37 Multiphase Flows: Turbulence 619 - Antonino Ferrante, University of Washington

8:00AM C37.00001 Wavelet-spectral analysis of droplet-laden isotropic turbulence, ANDREAS FREUND, ANTONINO FERRANTE, University of Washington — The energy spectrum for homogeneous isotropic turbulence is computed using the Fourier transform of the velocity field. In the case of multiphase turbulent flows, the velocity field is non-smooth at the interface between the carrier fluid and the dispersed phase, so the Fourier energy spectra exhibit spurious oscillations at high wavenumbers. An alternative definition of the spectrum uses the wavelet transform, which can handle discontinuities locally while additionally preserving spatial information about the field. We propose using the wavelet energy spectrum to study multiphase turbulent flows and a new decomposition of the wavelet energy spectrum into three contributions corresponding to the carrier phase, droplets, and interaction between the two. Lastly, we apply the new wavelet-decomposition tools in analyzing the DNS data of droplet-laden decaying isotropic turbulence. Our results show that, in comparison to the spectrum of the single-phase case, the droplets (i) do not affect the carrier-phase energy spectrum at high wavenumbers, (ii) increase the total energy spectrum at high wavenumbers by increasing the interaction energy spectrum at these wavenumbers, and (iii) decrease the total energy at low wavenumbers by increasing the dissipation rate at these wavenumbers.

8:13AM C37.00002 Direct numerical simulation of droplet-laden homogeneous shear turbulence, PABLO TREFZTZ-POSADA, ANTONINO FERRANTE, University of Washington — We have performed direct numerical simulations (DNS) of droplet-laden homogeneous shear turbulence (DLHST) at initial \( Re_\text{D} = \frac{1}{50} \) with 6260 droplets of diameter approximately equal to the Taylor lengthscale (i.e., 5% droplet volume fraction). The droplet to carrier-fluid density and viscosity ratios have been set to 10. The droplet Weber number based on the r.m.s. velocity has been varied between \( 0.1 \leq We_{\text{rms}} \leq 5 \). First, we present our numerical methods for overcoming the challenges of simulating DLHST. Then, we present the effects of varying the shear number (\( Sh \)) on the budget of turbulence kinetic energy (TKE). For example, in the two-fluid TKE equation the power of the surface tension is directly proportional to the rate of change of droplet surface area (with opposite sign). DNS results show the effects of shear on droplet deformation/breakup/coalescence and how this affects the power of the surface tension, and, thus, the evolution of TKE.
8:26AM C37.00003 Wavelet analysis of spectral energy transfer in two-way coupled particle-laden turbulence. MIRALIREZA NABAVI BAVIL, Arizona State University, MARIO DI RENZO, Center for Turbulence Research, Stanford University, Stanford, CA 94305, USA, JOEL INGLAE KIM, Arizona State University. This study investigates the effects of two-way coupling between the carrier and dispersed phases on the spectral transfer of turbulent kinetic energy (TKE) using the wavelet multiresolution analysis (WMRA). Direct numerical simulations of decaying homogeneous isotropic turbulence laden with inertial particles are performed at Stokes numbers $St = 0, 1$ and $10$ with the point-particle assumption. TKE decreases monotonically as $St$ increases, while this is not the case for the dissipation rate. A multiresolution analysis based on orthonormal wavelet transform is developed to evaluate spectral energy transfer due to different physical mechanisms near particle clouds interacting in two ways with the carrier-phase turbulence. Spectral statistics conditioned on the Eulerian particle number density are examined to understand the physical trends of spectral energy transfer as a function of Stokes number and discuss their significance in modeling.

8:39AM C37.00004 Cascades of bubbles in turbulent breaking waves. WAI HONG RONALD CHAN, PERRY JOHNSON, JAVIER URZAY, PARVIZ MOIN, Center for Turbulence Research, Stanford University. Turbulent breaking waves entrain air cavities that break up and coalesce to form polydisperse clouds of bubbles. A bubble-tracking algorithm is developed to identify bubble breakup and coalescence events in interface-capturing two-phase numerical simulations, and to quantify the resulting transfers of air between bubbles of different sizes. The evolution of the volume- and ensemble-averaged bubble size distribution resulting from imbalances of the averaged transfer fluxes is described by a population balance equation with models for breakup and coalescence kernels. The formalism resembles the phenomenology of the Richardson-Kolmogorov energy cascade in single-phase turbulence. In order to demonstrate the presence of a bubble cascade, the transfer of air mass in bubble-size space by breakup and coalescence is examined for an ensemble of simulations of turbulent breaking waves. For breakup, a quasi-local transfer is observed in which the net transfer of air across a certain bubble size primarily depends on the number and breakup frequency of bubbles of similar sizes. This quasi-locality suggests that the statistics of bubble breakup at intermediate sizes are largely independent of the smallest and largest bubbles, in support of the idea of a bubble breakup cascade. $1$

8:52AM C37.00005 Low pressure events of finite size bubbles in homogeneous isotropic turbulence. MEHEDI HASEN BAPPY, ALBERTO VELA-MARTIN, PABLO CARRICA, GUSTAVO BUSCAGLIA. None — The study of the behavior of bubbles in turbulent flow is fundamental to the understanding of many two-phase flow applications such as cavitation inception. As gas nuclei evolve in a turbulent flow, the pressure fluctuations can dip below the vapor pressure and trigger cavitation events. Pressure statistics along trajectories of finite bubbles in isotropic homogeneous turbulence is investigated using direct numerical simulations at two $Re = 150, 240$. A modified Maxey-Riley equation is solved to track bubbles of different sizes in the turbulence field. The results show that larger bubbles are more attracted by the vortex cores and spend longer times at low-pressure regions. This has significant impact on the PDF of the pressure experienced by the bubbles, as well as on the statistics of low-pressure events (i.e., average frequency, distribution of duration and inter-event delays). The effect of gravity on these statistics is also addressed. It is shown that gravity is a bubble transport mechanism that competes with flow induced pressure gradients, making the bubbles less sensitive to low-pressure vortex cores.

9:05AM C37.00006 Liquid film breakup induced by turbulent shear flow. MELISSA KOZUL, NTNU, PEDRO COSTA, KTH, JAMES R. DAWSON, NTNU, LUCIA BRANDT, KTH. Gas turbine engines commonly employ prefilming airlift atomizers for liquid fuel injection. Supplied from holes or slits upstream, the liquid fuel forms a thin film over the prefilming surface before being driven to the atomizing edge by a turbulent shear flow. The use of a second air stream on the other side of the prefilmer to prevent fuel accumulation means the breakup and eventual atomization of the liquid film occurs in the shear zone formed by the co-flowing air streams (Aigner & Wittig, J. Eng. Gas Turbines Power (1988) vol. 110, pp. 105 - 110). We consider a simplified numerical setup using a recently developed fluid model (Li et al., J. Comput. Phys. (2012) vol. 231, pp. 2328 - 2358) to simulate this multiphase problem. A liquid film is sandwiched between sheared turbulent gas flows from a precursor simulation, which serve to deform and then rupture the liquid film. The simplified setup allows us to systematically vary parameters such as film thickness and turbulent gas flow Reynolds number to gauge the effect upon momentum transfer into the initially stationary liquid film. Understanding and controlling the route to breakup and atomization of liquid fuels in such systems is of primary practical concern in modern gas turbine engine design.

9:18AM C37.00007 Turbulence modulations induced by a swarm of surfactant-laden droplets. GIOVANNI SOLIGO, ALESSIO ROCCON, ALFREDO SOLDATI, TU Wien; University of Udine. We use direct numerical simulations of turbulence coupled with a two-order-parameter phase-field method to describe the complex dynamics of a swarm of surfactant-laden droplets in turbulence. Two separate Cahn-Hilliard (CH) equations define the dynamics of the interface and of the local surfactant concentration. An interfacial term, based on the Korteweg tensor, accounts for the effect introduced by a surfactant-laden, deformable interface on the flow field. In particular, the interface term accounts for both normal (capillary) and tangential (Marangoni) stresses at the interface. The former originate from the presence of the interface, while the latter arise whenever surface tension gradients along the interface are present. These surface tension gradients originate from a non-uniform surfactant distribution. The presence of a surfactant-laden interface thus affect the local flow field and turbulence and modulates exchanges of momentum between the droplet fluid and the carrier fluid. Here we will present the effects of different reference (clean interface) surface tension values and different types of surfactant on these exchanges.

9:31AM C37.00008 Turbulence statistics in a negatively buoyant particle plume. EVAN VARJANO, ANKUR BORDOLOI, University of California Berkeley, CHRIS LAI, Los Alamos National Laboratory, LAURA CLARK, Stanford University, GERARDO VELIZ, Cornell University. Plumes containing bubbles, particles and droplets are found in many natural phenomena as well as industrial applications. We report herein the turbulence statistics in a negatively buoyant multiphase plume containing heavy particles. We generate the plume by continuously releasing nylon particles of size 2 mm inside a salt-water tank via screw-conveyor based release mechanism. The two phases are refractive-index matched, that enables us to measure the local velocity in the salt-water via stereoscopic particle image velocimetry. Besides some structural differences, the turbulence statistics in a particle plume resemble that measured in a bubble plume. The turbulent kinetic energy (TKE) production by particles (or bubbles) roughly balances the viscous dissipation, except near the plume centerline. We observe a ~3 power-law in the one-dimensional power-spectra of the velocity fluctuations that puts both the particle and bubble plume in a category different from single-phase shear-flow turbulence.
9:44AM C37.00009 Jammed emulsions via turbulent stirring. FEDERICO TOSCHI, IVAN GIROTTO, GIANLUCA DI STASO, KARUN DATADJEN, Eindhoven University of Technology, The Netherlands; ROBERTO BENZI, University of Rome Tor Vergata, Italy; PRASAD PERLEKAR, Tata institute of fundamental research, Hyderabad, India; ANDREA SCAGLIARINI, IAC-CNR, Rome, Italy — Stabilised dense emulsions are common in many foods and cosmetics products (e.g. mayonnaise). Such complex fluids, made of two immiscible fluid components and a stabilizing agent (e.g. surfactant), behave like an elastic solid below a critical yield stress and flow like a viscous fluid above it. More generally, stabilized emulsions display all the rich phenomenology and rheology typical of soft-glassy materials. Stabilized emulsions are often produced via large-scale turbulent stirring. This raises the questions of e.g. how the emulsion structure depends on the turbulent stirring protocol and what are the rheological properties of the obtained emulsion. We employ large-scale 3d direct numerical simulations based on the multi-component Lattice Boltzmann method and second-bond coupling to numerically investigate turbulent emulsification. We show that turbulence is effective in producing a jammed state. We report the protocol followed in order to achieve packing fractions above 70% of the dispersed fluid phase and we characterize the yield stress of the obtained emulsions. In general, our model can be used to investigate catastrophic phase inversion, an event occurring either when the forcing intensity exceeds a threshold value or for excessive depletion of the matrix phase.

9:57AM C37.00010 Impact of turbulence on cloud microphysics of water droplets population. MINA GOLSHAN, FEDERICO FRATERNALE, MARCO VANNI, DANIELA TORDELLA, Politecnico di Torino — This work focuses on the turbulent shear-less mixing structure of a cloud/clear-air interface with physical parameters typical of cumulus warm clouds. We investigate the effect of turbulence on the droplet size distribution, in particular we focus on the distributions broadening and on the collision kernel. We performed numerical experiments via Direct Numerical Simulations (DNS) of turbulent interfaces subject to density stratification and vapor density fluctuation. Specifically, an initial super-saturation around 2% kinetic energy of 100 cm²/s² are set in the DNSs. The Taylors Reynolds number is between 150 and 300. The total number of particles is around 5-10 millions, matching an initial liquid water content of 0.8 g/m³. Through these experiments, we provide a measure of the kernel of collisional integral operators to be compared with literature models [Saffman Turner, 1955] and possibly used inside drops Population Balance Equations (PBE) that include both processes of drops growth by condensation/evaporation and aggregation.

Sunday, November 24, 2019 8:00AM - 10:10AM — Session C38 Geophysical Fluid Dynamics Sediment Transport 620 - Bruce Sutherland, University of Alberta

8:00AM C38.00001 Dispersion and transport of tracer particles at an upper ocean front. VICKY VERMA, SUTANU SARKAR, University of California San Diego — Turbulence resolving simulations of upper-ocean fronts show the formation of thin filament structures during the evolution of baroclinic instability. The filaments develop large vertical vorticity and vertical velocity; furthermore, long filaments roll up to form coherent submesoscale eddies. The role of coherent structures, i.e. the vortex filaments and the eddies, in vertical and lateral transport and dispersion of particles has been studied for a submesoscale mixed layer front using tracer particles which advect with the local fluid velocity. The time evolution of tracer particles reveals stirring across the front, as well as vertical transport directed by the coherent structures. There are vortex filaments on both the heavier and lighter sides of the front that provide direct pathways for vertical transport. The filament on the heavier side downwells the local (heavier) fluid particles to the bottom, spiraling around the eddy, while the filament at the lighter side upwells the local (lighter) fluid particles to the surface. Subsequently, the downwelled and upwelled particles slowly adjust to a smooth stable profile. The effect of coherent structures on the dispersion of particles is studied using single-particle, two-particle and multi-particle dispersion statistics.

8:13AM C38.00002 Sediment transport and morphodynamics induced by a translating vortex. MATIAS DURAN-MATUTE, SAMUEL GONZALEZ-VERA, GERTJAN VAN HEIJST, Eindhoven University of Technology — We present experimental results on the effect of a translating monopolar vortex on a sediment bed. Experiments took place inside a water-filled square tank with a flat layer of small spherical particles at the bottom and placed on top of a rotating table. A vortex is generated on the tip of a plate perpendicular to one of the sidewalls by drastically changing the speed of the rotating table from a state of solid body rotation. This change was designed such that a residual current remained, advecting the vortex away from the plate. Strong-enough vortices bring sediment into suspension and transport it along their path. As the vortices weaken, the sediment settles back into the bed. This mechanism produces changes in the bed. Measurements of the flow were obtained through particle image velocimetry (PIV). The region of suspended sediment was reconstructed using images of the particles illuminated by a vertically oscillating horizontal laser sheet, and the changes in the bed thickness were measured with a photogrammetric technique. The strength of a vortex is the main parameter governing the capture and suspension of particles with similar settling velocity. A power law was found between the vortex strength and the net displaced particle volume.

8:26AM C38.00003 Two-way coupled direct numerical simulations of sinuous-crested bedforms. NADIM ZGHEIB, School of Engineering - Lebanese American University, S BALACHANDAR, Dept. of Mechanical and Aerospace Eng. - University of Florida — We present results from direct numerical simulations on the transition from straight-crested to sinuous-crested bedforms. The numerical setup is representative of turbulent open channel flow over an erodible sediment bed at a shear Reynolds number of Re₉ = 180. The immersed boundary method accounts for the presence of the sediment bed. The simulations are two-way coupled in the sense that the turbulent flow can erode and modify the sediment bed, and in turn, the sediment bed modifies the overlying flow. The coupling from the flow to the sediment bed occurs through the Exner equation, while the back coupling from the bed to the flow is achieved by imposing the no-slip and no-penetration boundary condition at the immersed boundary. The simulation setup is similar to that by Zgheib et al. (https://doi.org/10.1002/2017JF004398) except for the presence of sidewalls to better mimic laboratory flume conditions. Sidewalls are observed to significantly increase bedform sinuosity. We also investigate the effect of domain size and a zero sediment flux boundary condition on crestline sinuosity.

8:39AM C38.00004 Dune-dune repulsion

1. KAROL BACIK, University of Cambridge, SEAN LOVETT
2. Schlumberger Cambridge Research, COLM-CILLE CAULFIELD, NATHALIE VIPREND, University of Cambridge — Dunes are coherent sedimentary structures which arise spontaneously due to the dynamical interplay between granular matter and the flow of the overlying fluid. Natural dunes rarely occur in isolation. Aeolian dunes form vast dune fields and subaqueous bedforms occur in groups. As of now, the mechanisms which regulate the large scale organisation of dune fields are poorly understood. In particular it is unclear if the dune configurations we observe are stable or transient. Here we investigate the dynamics of a quasi-2D dune corridor using a subaqueous experiment in an annular geometry. We show that the corridor structure appears to be robust and that stabilisation is achieved by long range dune-dune interactions. Our experiments reveal that by altering the flow, dunes strongly affect the shape and the migration rate of their downstream neighbours which leads to an effective dune-dune repulsion. Here we discuss the physical origin of the repulsion mechanism and explore its consequences for the system-level dynamics of the dune corridor.

8:52AM C38.00005 Aggregate particle settling from a laboratory river plume

DAVID DEEPWELL, BRIANNA MUELLER, BRUCE SUTHERLAND, University of Alberta — Motivated by understanding how particles in sediment bearing river plumes ultimately settle, we present laboratory experiments of a constant-flux fresh water surface gravity current containing a low (< 1%) concentration of dense particles which initially overrides a saline ambient. Two classes of experiments were performed: 1) with a uniform density saline ambient fluid and 2) a two-layer ambient fluid. In both classes of experiments, collective settling combined with ambient recirculating flows result in particles settling out predominantly as a large single vertical plume. As the plume falls, the centre of the plume travels faster than the fluid around it causing an entrainment of neighbouring particles leading to a narrowing of the plume with depth. In a two-layer stratification with micrometer-sized particles, the settling is delayed at the interface between the upper and lower layers as a result of lighter fluid being dragged down with each particle in its surrounding viscous boundary layer thereby decreasing its effective density. The width and location of the sedimentation plume as well as the enhanced settling velocity of particles in the plume is characterized with respect to particle density and concentration.

9:05AM C38.00006 Strain-hardening evolution on sediment transport under cyclic laminar shear

1. FERNANDO CEZ, ERICK M. FRANKLIN, University of Campinas (UNICAMP), MORGANE HOUSSAIS, Levich Institute, City College of CUNY, PAULO E. ARRATIA, DOUGLAS J. JEROLMACK, University of Pennsylvania — Fluid-driven granular flows are common in nature and industry, yet difficult to understand. We employ a large eddy simulation (LES) code with micrometer-sized particles sheared by a laminar flow; this allows visualization of particle transport throughout the bed. We introduce stepped cycles of fluid shear and examine the downward propagation of an “unjamming” front, which marks the boundary between a granular fluid and a creeping solid. Repeated shear cycles give rise to strain hardening, as the fluidized layer thins over progressively longer times. Such experimental results are compared to numerical simulations: isotropic grain fabric structures aligned with the applied shear. When shear direction is reversed, the bed recovers some (but not all) of its initial mobility. Strain hardening, associated compaction and grain-fabric formation, occur in the observed creep regime. Beyond a critical shear rate, grains are fluidized resulting in dilation and destruction of granular fabrics. Results explain puzzling observations of bed-load hysteresis in natural rivers and delineate the transport regimes under which memory is created and destroyed in sedimentary beds.

9:18AM C38.00007 LES of a large-scale river with arbitrarily complex bathymetry and wall-mounted structures

KEVIN FLORA, ALI KHOSRONEJAD, Stony Brook University — High-fidelity numerical simulation of flow in natural riverine environments is essential for understanding the potential impacts of flood events on infrastructure and the potential morphological changes to the channel. However, due to the bathymetric complexity and unique shapes of man-made structures located in the flow, it is very challenging to create high-fidelity models which accurately depict the dominant three-dimensional flow structures. Such flow dynamics often lead to the erosion of the banks, scour of infrastructure foundations and overall transport of sediment in the flow. As a result, simplified models are often used in engineering practice, but these models fail to accurately simulate important features of flow. We employ a large eddy simulation (LES) code to model flow around four bridge piers in the American River in California to study the qualitative and quantitative differences in the resulting data. Specifically, this study compares the results of the LES code with more simplified hydrodynamic models to assess the difference in the estimated bed shear stress distribution and the overall impacts of the bridge structures on the turbulence.

9:31AM C38.00008 Fluid-driven transport of spherical sediment particles: from discrete simulations to continuum modeling

QIONG ZHANG, KEN KAMRIN, Mechanical Engineering, Massachusetts Institute of Technology, ERIC DEAL, TAYLOR PERRON, EAPS, Massachusetts Institute of Technology, JEREMY VENDITTI, Simon Fraser University, SANTIAGO BENAVIDES, MATTHEW RUSHLOW, EAPS, Massachusetts Institute of Technology — Empirical bedload transport expressions commonly over- or underpredict sediment flux by more than a factor of two, even under controlled laboratory conditions. In this work, a novel Element Method and Lattice Boltzmann Method are coupled together to simulate 3D fluid-driven transport problems, in which the spherical sediment particles are fully resolved. After comparisons with flume experiments are made to test the numerical simulations, the grain-scale physics is studied, such as the role of the gravitational forces and other order descriptions of the grain motion. A more robust continuum model, unifying empirical models under various conditions and in different regimes, is further proposed based on the new grain-scale understanding of the mechanisms.

9:44AM C38.00009 Three-phase flow LES of flash floods in a real-life desert stream

1. ALI KHOSRONEJAD, KEVIN FLORA, Stony Brook University, ALI KHOSRONEJAD TEAM — We present a fully coupled three-phase flow model of air-water-sediment to simulate numerically the propagation of flash floods in field-scale dry-bed desert streams. The turbulent flow and free surface of the flash flood are computed using large-eddy simulation (LES) level-set method, respectively. The evolution of stream morphology, due to the propagating flood on the mobile bed, is calculated using an Eulerian morphodynamics model based on the curvilinear immersed boundary method. We demonstrate the capabilities of our numerical framework by applying it to simulate a flash flood event in a 0.65 km-long reach of a desert stream in California. The simulation result of the stream includes a number of bridge foundations. Simulation results of the model for the flash flood event revealed the formation of highly complex flow field and scour patterns within the stream. Moreover, our simulation results show that most of the scour processes takes place during the steady phase of the flash flood. The transient phase of the flash flood is rather short and contributes to a very limited amount of erosion within the desert stream. Acknowledgment: support for this work is provided by NSF award EAR-1823121.
9:57AM C38.00010 Euler-Lagrange Simulations of Bedload Transport and Bedform Generation1, LIHENG GUAN, JORGE SEBASTIAN SALINAS, S. BALACHANDAR, University of Florida — Bedload transport is a subset of sediment transport in which the sediment particles rolls, slides and saltates under the influence of the overlying flow field. The particles in the bedload occasionally gets lifted and gets suspended at high enough flow rate. In this work, the bedload transport problem is investigated by performing numerical simulations with implementation of Euler-Lagrange point-particle approach. The fluid field is solved on the Eulerian reference frame while the motion of sediment particles are tracked on the Lagrangian reference frame. Moreover, the collisions between particles are handled using a soft-sphere collision model which includes both a normal collision force and a tangential collision force. Additionally, the rotational motion of particles is also considered in this work. In the bedload transport simulation, a fully developed turbulent channel flow is imposed over an initially flat bed. Various bedform structures, from longitudinal streaks to ripples, arise as the sediment bed evolves. The results are compared with those using Exner’s equation.

Sunday, November 24, 2019 10:38AM - 12:38PM – Session D01 Awards Session: Presentation of Awards and DFD Fellowships (Otto LaPorte Lecture, Stanley Corrsin Award) 6abc - Detlef Lohse, University of Twente: Karen Daniels, NC State University

10:38AM D01.00001 PRESENTATION OF AWARDS AND DFD FELLOWSHIPS

11:08AM D01.00002 Otto LaPorte Lecture: Experiments in High Reynolds Number Flows1, ALEXANDER SMITS, Princeton University — To attain a very large range of Reynolds numbers in the laboratory, it is convenient to use high-pressure air. We have made extensive use of this approach to study the behavior of full-developed pipe flow, turbulent boundary layers, and the wakes downstream of bodies-of-revolution. I will summarize some of the major results obtained for the pipe and boundary layer, including the scaling of the mean velocity profile, the streamwise turbulence intensity, and the spectra. I will also discuss some present and future directions of this research, which largely focus on high Reynolds number non-canonical flows.

1This work has been supported by ONR, most recently through Grant N00014-17-1-2309.

11:53AM D01.00003 Stanley Corrsin Award Talk: From Microstructure to Models – Fluid Mechanics of Suspensions1, JEFFREY F MORRIS2, Levich Institute, CUNY City College of New York — Suspensions of particles in Newtonian liquids are simple complex fluids. Describable by just a handful of macroscopic variables, suspensions are in one sense simple; but the microscopic state is responsive to variation of these variables, making the flow properties non-Newtonian, and hence these are complex fluids. Our work is motivated by the scientific goal of developing a fluid mechanics of the bulk suspension behavior, toward a framework allowing analysis and computation; the hope is that this will expand understanding of suspensions found in engineering and the environment. Progress toward this goal often benefits from examination of the microscopic mechanics. Particle migration and its basis in rheological properties will be discussed, along with the microstructure of particles leading to these properties. Phenomena in extremely dense suspensions – shear thickening and jamming – will be discussed with an emphasis on how these motivate a shift in focus, from the particles to the force networks developed under flow. The prior Stokes-flow examples will be complemented by presentation of inertial transitions observed in Taylor-Couette flow of suspensions, to illustrate challenges faced in developing a true fluid mechanics of these mixtures.

Sunday, November 24, 2019 2:03PM - 2:38PM – Session E02 Invited Talk: Advancing understanding of turbulence through extreme-scale computation 6b - Katepalli Sreenivasan, NYU

2:03PM E01.00001 Understanding of turbulence through extreme-scale computation1, P.K YEUNG, Georgia Institute of Technology — Since its beginnings in the early 1970s, direct numerical simulation of turbulence in canonical geometries has always been the computational approach that is physically the most accurate, a massive source of data, and a grand challenge in high-performance computing, whose definition has evolved by many orders of magnitude since then. In particular, challenges driving the need for ever-larger simulations on a 3D periodic domain include, to name a few, fine-scale intermittency at high Reynolds number, with stringent resolution requirements, the mixing of a passive scalar of low molecular diffusivity, and the motion of fluid and inertial particles in a Lagrangian framework. Most known state-of-the-art simulations have employed massive CPU-based parallelism, which is ultimately limited by communication costs traceable to the multi-dimensional nature of the Navier-Stokes equations. However, current trends in pre-Exascale leadership computing are pointing to the growing importance of heterogeneous platforms, whose principal advantage is accelerated computation and whose full exploitation requires a new paradigm in code development. In this talk, we will discuss the major features of a new pseudo-spectral code which has been shown to scale satisfactorily up to a problem size of 184323 resolution on the currently world’s fastest GPU-based “Summit” supercomputer located at the Department of Energy Oak Ridge National Laboratory. We show that new simulations at this resolution are enabling significant advancements in studies of small-scale turbulence, with emphasis on extreme events where fluctuations of energy dissipation rate and enstrophy (vorticity squared) can reach O(103) times of the mean value or higher. We also discuss briefly how recent simulations at resolution 81923 or higher are contributing to progress in the study of turbulent mixing, for both passive and active scalars in non-unity Schmidt number regimes.

There is a wide range of highly important applications, not least the leads to the enhanced irreversible transport of heat and other scalars (such as salt and pollutants) in density-stratified fluids is a fundamental problem. What we do not know?

2:03PM E02.00001 Living flow networks, ELENI KATIFORI, University of Pennsylvania — Complex life larger than a humble nematode would not be possible without a circulatory system. Plants, fungi, and animals have developed vascular systems of striking complexity to solve the problem of long distance nutrient delivery, waste removal, and information exchange. These biological flow systems are frequently not static, but dynamically alter the diameters of their vessels in order to optimally achieve their intended function. The conductance of these vessels does not have to be linear, although it is frequently treated as such. Inspired by haemodynamic oscillations in the cortex, in this talk we explore how a superficially simple system of laminar flow vessels can sustain dynamic local oscillations, even in the absence of time varying boundary conditions. We will show how these non-linear conducting vessels redirect high volumes of flow to different locations of the network. We will present how the dynamics of this system is akin to an excitable system without any explicit refractory period in the vessel response. Last, we will discuss how we can harness the interplay of network topology and fluid dynamics to control flow in unexpected ways, and what this dynamic flow network behaviour can tell us about living systems.

Sunday, November 24, 2019 2:03PM - 2:38PM –
Session E03 Invited Talk: Lagrangian turbulent thermal convection 6e - Nicolas Mordant, LEGI, University Grenoble-Alps

2:03PM E03.00001 Lagrangian turbulent thermal convection1. MICKAL BOURGOIN, Physics Laboratory, CNRS / ENS de Lyon — Thermally driven turbulence plays an important role in numerous areas of science and technology. Many natural (atmospheric and oceanic dynamics, processes in planetary cores, etc.) and industrial (cooling of buildings, heat exchangers, etc.) flows are indeed controlled by thermal convection, and often exhibit peculiar inhomogeneity and non-stationnary behavior. While a prolific literature exists regarding transport phenomena for homogeneous, isotropic and stationary turbulence, understanding the transport properties of thermal turbulence remains a real challenge, especially from the Lagrangian prospect. In this presentation, recent experimental results on the Lagrangian description of thermal turbulence in Rayleigh-Bnard convection will be presented. The specific roles of small-scale turbulence and large scale inhomogeneities and unsteadiness will be discussed, revisiting both the Lagrangian dynamics of single particles and the celebrated pair dispersion problem.

Sunday, November 24, 2019 2:43PM - 3:18PM –
Session F02 Invited Talk: Reduced Order Modeling of Blood Flow 6c - Rajat Mittal, Johns Hopkins University

2:43PM F02.00001 Reduced Order Modeling of Blood Flow, SHAWN SHADDEN, UC Berkeley — Image-based blood flow modeling has become a cornerstone in cardiovascular research and has recently gained regulatory approval and clinical adoption for diagnosis of cardiovascular disease. This technology combines medical imaging with advanced computational fluid dynamics modeling to predict flow and pressure in regions of the cardiovascular system. Toward the same goal, I will discuss combining medical imaging with simplified, reduced-order modeling (ROM) of blood flow. These ROM developments enable new possibilities to use modeling for timely decision support in clinical settings, and improve the abilities to perform data assimilation, optimization, parameter tuning, uncertainty quantification and sensitivity analysis in cardiovascular modeling applications. I will discuss the underlying methodologies, and comparison of our ROM approaches against current states-of-the-art.

Sunday, November 24, 2019 2:43PM - 3:18PM –
Session F03 Invited Talk: Open questions in turbulent stratified mixing: Do we even know what we do not know? 6e - Peter Diamessis, Cornell University

2:43PM F03.00001 Open questions in turbulent stratified mixing: Do we even know what we do not know? C. P. CAULFIELD, BP Institute & DAMTP, University of Cambridge — Understanding how turbulence leads to the enhanced irreversible transport of heat and other scalars (such as salt and pollutants) in density-stratified fluids is a fundamental and central problem in geophysical and environmental fluid dynamics. There is a wide range of highly important applications, not least the description and parameterization of diapycnal transport in the world’s oceans, a key area of uncertainty in climate modelling. Recently, due not least to the proliferation of data obtained through direct observation, numerical simulation and laboratory experimentation, there has been an explosion in research activity directed at improving community understanding, modelling and parameterization of the subtle interplay between energy conversion pathways, turbulence, and irreversible mixing in density-stratified fluids. However, as I will discuss in this talk, there are still leading order open questions and areas of profound uncertainty concerning turbulent stratified mixing. Therefore, I will present a personal perspective on some priorities for further research into this hugely complex, important and fascinating fluid dynamical challenge.
3:48PM G01.00001 Collapse of multiple holes in an unbounded liquid film, MICHAEL EIGENBROD, STEFFEN HARDT, Institute for Nano- and Microfluidics, TU Darmstadt — We study experimentally and theoretically the collapse of multiple holes in a liquid film. The time evolution of an ensemble of holes is examined using high-speed videomicroscopy and characterized by the time-dependence of the hole shapes. An analytical formula for the potential energy difference between an unbounded collapse of multiple holes in a liquid film. The time evolution of a multi-hole arrangement in a highly viscous film can be predicted through steepest descent of the potential energy in a confinement space representing the shapes of the holes. The theoretical model for the time evolution of the system if confirmed by experimental results for the collapse of multiple nearly circular holes.

4:01PM G01.00002 Thermal rupture of a free liquid sheet, JENS EGGERS, University of Bristol, GEORGY KITAVTSEV, University of Oxford, MARCO FONTELOS, Instituto de Ciencias Matematicas — We consider a free liquid sheet, taking into account the dependence of surface tension on the temperature or concentration of some pollutant. The sheet dynamics are described within a long-wavelength description. In the presence of viscosity, local thinning of the sheet is driven by a strong temperature gradient across the pinch region, resembling a shock. As a result, for long times the sheet thins exponentially, leading to breakup. We describe the quasi-one-dimensional thickness, velocity and temperature profiles in the pinch region in terms of similarity solutions, which possess a universal structure. Our analytical description agrees quantitatively with numerical simulations.

4:14PM G01.00003 Optimal Capillary Breakup Rheometer Procedures for Newtonian Filaments, SUBRAMANIAM BALAKRISHNA, WILLIAM SCHULTZ, University of Michigan (Ann Arbor, MI, US) — The differential analysis of McCarron et al (2016) determines the surface tension to viscosity ratio from the symmetry point of an unsteady Newtonian film profile and its derivatives. The experimental challenges are twofold: (a) the fourth derivative of the free surface radius is required and difficult to extract from low-resolution, pixelated and possibly noisy images and (b) the sensitivity of the surface tension to viscosity ratio to the stretch history. In particular, for filament evolution dominated by viscosity and surface tension, stretching too quickly makes the free surface profile nearly cylindrical, while stretching too slowly yields a quasi-static profile with no viscous information. We give strategies that optimize the ratio measurement including use of higher-order finite difference stencils and measurements made during stretch.

4:27PM G01.00004 ABSTRACT WITHDRAWN

4:40PM G01.00005 Interfacial perturbation classification of a fluid impulsively driven through a honeycomb mesh into a gas-filled cavity, TAKIAH EBBS-PICKEN, RUBERT MARTIN PARDO, McGill University, DAVID PLANT, General Fusion, ANDREW HIGGINS, JOVAN NEDIC, McGill University, MCGILL UNIVERSITY COLLABORATION, GENERAL FUSION COLLABORATION — We investigate the development of perturbations on a liquid-gas interface created by the impulsive motion of fluid through a honeycomb mesh. The effects of implosion speed, mesh geometry, angular velocity of the interface, and initial liquid depth relative to the mesh were experimentally investigated to determine their effects on the geometry of the perturbations formed. An experimental arrangement was created that allowed for the visualization of the cavity surface, and a classification based on the perturbation geometry was developed. Five different perturbations were observed, which were classified as follows: none, wavy, sharp, jetting and complex. The results showed that the parameter which had the largest impact on the initial perturbation growth was the fill depth of the liquid relative to the mesh, while the angular velocity and implosion speed had limited effects.

4:53PM G01.00006 The natural breakup length of a steady capillary jet, SASA BAJT, HENRY CHAPMAN, MAX WIEDORN, JURAJ KNOSKA, YANG DU, Center for Free-Electron Laser Science, Deutsches Elektronen Synchrotron (DESY), Notkestrasse 85, 22607 Hamburg, Germany, MICHAEL HEYMAN, Dept. Physics, University of Hamburg, Luruper Chaussee 149, 22761 Hamburg, Germany, BRAULIO GANAN-RIESCO, Ingenieria Tecnologias S.L., 41000 Carac, Sevilla, Spain, JOSE M. LOPEZ-HERRERA, MIGUEL A. HERRADA, FRANCISCO CRUZ-MAZO, ALFONSO M. GANAN-CALVO, Universidad de Sevilla, ETSI, 41092 Sevilla, Spain — The averaged natural breakup length of capillary jets ejected in inactive environments are determined by the liquid properties, its velocity and its diameter. Despite its theoretical and applied interest, a general procedure to predict that length has not been proposed yet. Here we describe and quantify the energy route that sets it. We find that the underlying mechanism that determines that length is the short-term transient growth rate of perturbations excited by the jet breakup itself. We propose a perturbation analysis of the time averaged energy conservation equation in the absence of body forces. The balance of total energy rates due to the perturbations is reduced, by dimensional analysis, to a closed algebraic expression with two universal constants. These constants are calculated by optimal fitting of a large set of experiments from diverse sources, experimental and numerical, which confirm the universal scaling law found.

5:06PM G01.00007 Modelling of perturbations in the surface of a cylindrical imploding rotating cavity, RUBERT MARTIN PARDO, McGill University, DAVID PLANT, General Fusion, JOVAN NEDIC, McGill University, GENERAL FUSION COLLABORATION — A cylindrical cavity is formed by rotating a liquid to solid body rotation resulting in a cylindrical liquid shell surrounding a gas-filled cavity. As this cavity is radially collapsed by pushing the fluid through a honeycomb mesh, perturbations begin to form on the interface. The dynamics of this perturbation can be well modelled by a second-order ODE and, as such, the initial velocity and amplitude of the perturbation have a decisive role on the exterior behavior of the roughness of the surface during the implosion. It will be shown how this initial perturbation, in turn, depends on different control parameters, namely the driving pressure profile, the rotation rate of the system, the initial liquid depth and the mesh geometry. A model is developed to account for this relation. The cavity surface was measured using high-speed videography and surface tracking digital techniques for a range of values of the control parameters sufficient to capture the change from a rough cavity surface to a smooth interface.

Expressions for temperature jumps and phase change rates are obtained from theoretical considerations and augmented by MD simulations.

Accounting for jump-conditions across phase interfaces using explicit interface tracking and discontinuous interpolation only at the interface.

Continuity/discontinuity. In this study, we explore the effect of temperature discontinuities at liquid-vapor interfaces before the system reaches a quasi-steady state condition; however, a dissimilar temperature profile was observed with the assumption of temperature entrainment minimization as well as fill ratio and optimized geometric dimensions for maximizing axial heat flow.

We exploit ideas otherwise applied to plastron respiration by aquatic insects. We thereby reject the popular simplification that the three-phase functioning of the heat pipe, the interface shape dictating the degree of capillary pumping that occurs. In formulating our mathematical model, this shape changes owing to a change of operating conditions. Far from being of academic interest, these details are essential to the effective shape change in total flow Q along the wedge is used to determine the mass flux from the liquid meniscus into the vapor due to phase change.

An imposed temperature gradient gives rise to Marangoni flow in the direction of decreasing temperature. The fluxes significantly in a quasi-steady state condition; however, a dissimilar temperature profile was observed with the assumption of temperature continuity/discontinuity. In the constrained vapor bubble system, designed by the group of J. Plawsky, liquid-vapor mixture inside an elongated cuvette of rectangular cross-section is subject to axial temperature gradients resulting in phase change and complex flow patterns. Experimental studies of this system have been conducted on the ground and onboard the International Space Station. A number of unexpected phenomena, most notably flooding of the hot end of the cuvette, were discovered in the microgravity experiment. In the present study, we focus on mathematical models designed to explain some of these phenomena via a study of corner flows driven by both Marangoni and an opposing capillary flow due to changes in temperature and curvature of the menisci respectively along the wedge. Also, phase change takes place at the liquid vapor interface and, depending on the location, can be either evaporation or condensation. A model is presented for a steady state corner wedge flow and compared with experimental observations. An imposed temperature gradient gives rise to Marangoni flow in the direction of decreasing temperature. The change in total flow Q along the wedge is used to determine the mass flux from the liquid meniscus into the vapor due to phase change.

4:27PM G02.00004 Liquid-Vapor Interface Configuration for Capillary Flow in a Heat Pipe. MUHAMMAD RIZWANUR RAHMAN, PRASHANT WAGHMARE, MORRIS R. FLYNN, University of Alberta — The shape of the liquid-vapor interface within a heat pipe wick is responsive to the wetting characteristics of the working fluid, wick geometry and other operational variables. This study critically investigates the underlying physics that dictate the interface shape and the manner in which this shape changes owing to a change of operating conditions. Far from being of academic interest, these details are essential to the effective functioning of the heat pipe, the interface shape dictating the degree of capillary pumping that occurs. In formulating our mathematical model, we exploit ideas otherwise applied to plastron respiration by aquatic insects. We thereby reject the popular simplification that the three-phase contact point is somehow anchored at a fixed elevation within the wick. Although multiple solutions are predicted, corresponding to different interface shapes, only one is mechanically stable and therefore physically-acceptable. When coupled with a complementary thermodynamic model, the unique interface shape can be predicted for prescribed operating conditions. Such information offers insights on the recess depth for entrainment minimization as well as fill ratio and optimized geometric dimensions for maximizing axial heat flow.
4:40PM G02.00005 Core Annular Flow Theory as Applied to the Adiabatic Section of Heat Pipes1, AISHWARYA RATH, MORRIS R. FLYNN, University of Alberta — Core annular flow theory is used to model the parallel flow of fluids of different phases and has been applied to industrial applications from bitumen hydrotransport to sub-aqueous drag reduction. Here we consider the extension of core annular flow theory to the study of the adiabatic section of heat pipes. Our aim is to develop a first-principles estimate of the conditions necessary to maximize the (counter) flow of liquid and vapor and, by extension, the axial flow of heat. Both planar and axisymmetric geometries are examined. Moreover, we consider heat pipes either containing or devoid of a wick. In these two respective cases, the peripheral return flow of liquid is driven by capillarity and by gravity. Our model is used to predict velocity profiles and the appropriate pressure gradient ratio (vapor-to-liquid). We further obtain estimates for the optimum thickness of the liquid layer. Note finally that when the liquid flow occurs via capillary pumping, there is a minimum surface tension below which the wick cannot supply a sufficient flow of liquid. We characterize this critical point in terms of e.g. the viscosity ratio, the density ratio and the wick depth, porosity and permeability.

4:53PM G02.00006 A non-Reynolds lubrication model and application to droplet levitation1, SHINTARO TAKEUCHI, JINGCHEN GU, Osaka University, AMARYU BARRAL, Tokyo University of Agriculture and Technology, Ecole polytechnique, YOSHIYUKI TAGAWA, Tokyo University of Agriculture and Technology, NRL COLLABORATION, LEVITATION COLLABORATION — An attempt for extending the applicability of the Reynolds lubrication theory is presented. By considering a larger surface-to-surface distance than that for the Reynolds lubrication theory, the effect of the non-negligible pressure gradient in the surface-normal direction is incorporated into the lubrication model. The analysis shows that the local pressure is separated into (i) a base component satisfying the Reynolds lubrication theory and (ii) an adjusting component varying in the surface-normal direction, and the second component is found to be related with the velocity of the local Couette-Poiseuille flow. The lubrication model is verified in a non-Reynolds regime of a flow between a moving curved object and stationary object, and good agreement in the pressure distributions by analytical and numerical methods is observed in both wall-normal and longitudinal directions. The lubrication model is also applied to a droplet levitation problem over a moving wall (Sawaguchi 2019) involving a µm-thin air film, and the levitation lift reproduced from the full drop profile is found to provide a more accurate and complete view of the levitation problem.

5:06PM G02.00007 Population Balance Modelling and CFD analysis in a Multi-scale Approach for Flash Nano-precipitation1, ALESSIO LAVINO, Politecnico di Torino, PAOLA CARBONE, University of Manchester, DANIELE MARCHISIO, Politecnico di Torino, OMAR MATAR, Imperial College London — Polymer nanoparticles (NP) formation is investigated by a multi-scale modelling approach focusing on poly-e-caprolactone (PCL) self-assembly in acetone-water mixtures via flash nano-precipitation (FNP). The control of the final NP size at the outlet of the mixer and the evolution of the particle size distribution, cluster mass distribution (CMD), are guaranteed by a suitable population balance model (PBM) closed with the quadrature method of moments (QMOM). The CMD moments are transported and coupled with computational fluid dynamics (CFD). NP size is characterised in terms of mean radius of gyration, expressed through Flory theory. Molecules are treated as building blocks undergoing aggregation once the solubility limit is exceeded. The rate at which two NP collide and aggregate is expressed by the aggregation kernels, built upon molecular dynamics simulations. Turbulent fluctuations on NP formation are taken into account thanks to the direct quadrature method of moments coupled with the interaction-and-exchange-with-the-mean (DQMOM-IEM) method. Favre-averaged continuity and Navier-Stokes equations are implemented, in order to consider the density fluctuations of the system. The model is validated against experiments, showing an excellent agreement.

Sunday, November 24, 2019 3:48PM - 5:19PM – Session G03 Focus Session: Fish Swimming Kinematics and Hydrodynamics I

3:48PM G03.00001 Fish out of water: hydrodynamics from swimming to jumping1, ALEXANDRA H. TECHET, Massachusetts Institute of Technology — Aquatic jumping is widely revered with awe by humans, as evidenced in the popularity of the Discovery Channels “Shark Week” episodes on jumping sharks. Jumping by any organism requires high bursts of power and muscular coordination. Aquatic jumpers in particular must produce thrust in manners compatible with the transition from one fluid media to the next, specifically accounting for the drastic drop in fluid density (and thus force-producing ability) between water and air. Jumping for food requires more precision than jumping for migration or escape. Organisms ranging in size from large marine mammals and sharks (length O(10m)) to small copepods (length O(0.01m)) have developed aquatic jumping strategies compatible with their size and survival goals (e.g., prey capture, escape, mating or migration). Larger animals tend to employ burst swimming for short periods before water exit, and smaller swimming fish tend to use S- or C-start acceleration maneuvers to generate jump thrust. Even smaller organisms such as copepods exhibit jumping behaviors using unique hydrodynamic mechanisms for impulsive vortical formation. However, water escape by engineered machines has yet to be mastered. Water-to-air transitions in vehicles are typically accomplished through high-momentum, high fuel consumption, artificial jets or propellers. The synergistic multi-propulsor relationships identified from fish swimming investigations could be paradigm-shifting for the design of biotinspired multiphase vehicles. This talk will discuss how studies of freely swimming fish and flapping foils can inform jumping analysis and our understanding of fin-fin interactions in complex fish maneuvers.

as well as in swimming at various speeds.

We quantitatively investigated the burst-and-coast gaits that minimize CoT in transport with and without target distance, less than that during undulatory propulsion at the same speed, properly switching between undulatory propulsion and coasting may reduce the cost of transport. We investigated the burst-and-coast gaits that minimize CoT during cyclic swimming. The derived optimal strategies for various types of swimmers all suggest that fish should change tail-beat frequency to control speed with a nearly constant tail-beat amplitude. Because drag during coasting is much less than that during undulatory propulsion at the same speed, properly switching between undulatory propulsion and coasting may reduce the cost of transport. We quantitatively investigated the burst-and-coast gaits that minimize CoT in transport with and without target distance, as well as in swimming at various speeds.

constructing a simulation-based performance map in the frequency-amplitude parameter space, we obtained the speed-specific optimal strategy that minimizes the cost of transport (CoT) during cyclic swimming. The derived optimal strategies for various types of swimmers all suggest that the drag magnitude is strongly influenced by the undulatory kinematics, much exceeding that of a rigid fish gliding at the same speed. By swimming fish, and found that the scaling trend of drag during undulatory swimming follows that of a rigid three-dimensional object, while Paris Diderot 7, France — Fish undulatory kinematics is not only a means to overcome drag, but also a source of it. By utilizing a computational approach that couples the Navier-Stokes equations with the equations of undulating body motion, we decomposed thrust and drag in swimming fish, and found that the scaling trend of drag during undulatory swimming follows that of a rigid three-dimensional object, while the drag magnitude is strongly influenced by the undulatory kinematics, much exceeding that of a rigid fish gliding at the same speed. By constructing a simulation-based performance map in the frequency-amplitude parameter space, we obtained the speed-specific optimal strategy that minimizes the cost of transport (CoT) during cyclic swimming. The derived optimal strategies for various types of swimmers all suggest that fish should change tail-beat frequency to control speed with a nearly constant tail-beat amplitude. Because drag during coasting is much less than that during undulatory propulsion at the same speed, properly switching between undulatory propulsion and coasting may reduce the cost of transport. We quantitatively investigated the burst-and-coast gaits that minimize CoT in transport with and without target distance, as well as in swimming at various speeds.

Numerical analysis of the force generation mechanism in a stingray inspired circular plan-forms. Seth Brooks, Melissa Green, Syracuse University — A two-degree-of-freedom fish model was investigated to understand the phenomenological relationship between simplified fish body kinematics and wake vortex dynamics. Its design, construction, and actuation provide control over frequency, tail (posterior half of body) angle, caudal fin to tail relative angle, and phase offset between the two angles. The frequency and phase offset were fixed for all cases in the current work while the tail and caudal fin angles were varied to create eight cases. Phase-averaged velocity data was collected beside the posterior half of the model as well as in the wake of the model. Data was obtained using stereoscopic particle image velocimetry at multiple planes along the entire span of the caudal fin. It was found that the body-generated vortices did not significantly interact with the caudal fin. The caudal fin leading edge vortex detaches from the surface sooner in cases with larger maximum tail angle. The total circulation generated at the caudal fin trailing edge was found to be sensitive to trailing edge velocity while being relatively insensitive to freestream velocity. Finally, the shedding of vortices from the caudal fin trailing edge was found to usually, but not always, coincide with periods of trailing edge deceleration.

The ground effect on anguiliform swimming performance. Mohsen Daghooghi, University of Houston-Clear Lake, Uchenna Ogunka, Iman Borazjani, Texas A&M University — Sea lampreys are found in the northern and western Atlantic Ocean along shores of Europe and North America as well as in the shores of Great Lakes and nearby rivers. This species is anadromous; from their lake or sea habitats, they migrate up rivers to spawn. In other words, they specialized to efficiently swim not only in deep but also in shallow waters. Various studies have shown that certain types of fish swim close to a solid surface and when it is unconstrained or freely swimming in the cross-stream direction. It was found that the foil has stable equilibrium altitudes: the time-averaged lift is zero at certain altitudes and acts to return the foil to these equilibria. These stable equilibrium altitudes exist for both constrained and freely swimming foils and are independent of the initial conditions of the foil. In all cases, the equilibrium altitudes move farther from the ground when the Strouhal number is increased or the reduced frequency is decreased. Potential flow simulations predict the equilibrium altitudes to within 3-11%, indicating that the equilibrium altitudes are primarily due to inviscid mechanisms. In fact, it is determined that stable equilibrium altitudes arise from an interplay among three time-averaged forces: a negative jet deflection circulatory force, a positive quasi-static circulatory force and a negative added mass force. At equilibrium, the foil exhibits a deflected wake and experiences a thrust enhancement of 4-17% with no penalty in efficiency as compared to a pitching foil far from the ground.

The computational resources for this study were partly provided by the High-Performance Research Computing (HPRC) group at Texas A&M University.
5:06PM G03.00007 Fluid-mediated stable equilibria for two-dimensional schools\textsuperscript{1}. MELIKE KURT, KEITH MOORED, Lehigh University, MOORED LAB TEAM — Fish oscillate their fins and tails and create disturbances in the form of vortical wake structures. These fish often operate in groups or collectives, which alter these structures and consequently their force production. In the 1970s, Sir James Lighthill hypothesized that for fast locomotion, hydrodynamic interactions could give rise to orderly patterns in fish collectives without the need for collective decision-making or active control mechanisms. Previous studies tested this hypothesis by studying the force equilibria in one-dimensional schools where swimmers are arranged along the stream-wise direction in in-line configurations. Here, our goal is to investigate the existence of these equilibrium points in two-dimensional schools by varying synchrony, as well as the cross-stream and stream-wise spacings between two hydrofoils. To this end, flow field analysis, as well as force measurements, will be conducted to draw a relation between the fluid-mediated forces and vortical interactions within the flow-field.

Sunday, November 24, 2019 3:48PM - 5:06PM — Session G04 Suspensions: General III 203 - Alexander Zinchenko, University of Colorado Boulder

3:48PM G04.00001 Tunable solidification of cornstarch under impact: how to make someone walking on cornstarch sink. RAN NIU, MEERA RAMASWAMY, Cornell University, CHRISTOPHER NESS, University of Cambridge, ABHISHEK SHETTY, Anton Paar USA, ITAI COHEN, Cornell University — Hundreds of Youtube videos with millions of views show people running on a mixture of cornstarch and water. These videos demonstrate a general phenomenon in fluid mechanics that dense shear thickening suspensions can solidify under impact. Such processes can be mimicked by impacting and pulling out a solid plate from the surface of a thickening cornstarch suspension. Here, using both experiments and simulations, we show that by applying fast oscillatory shear transverse to the primary impact or extension directions we can tune the degree of suspension solidification. The forces acting on the impacting surface can be modified by varying the dimensionless ratio of the orthogonal shear to the compression and extension flows. Simulations show that varying this parameter changes the number of particle contacts governing solidification. To demonstrate this strategy in an untethered context, we show that the sinking speed of a cylinder dropped onto the cornstarch suspension can be varied dramatically by changing this dimensionless ratio. These results suggest that applying orthogonal shear in the context of people running on cornstarch would de-solidify the suspension and cause them to sink.

4:01PM G04.00002 Dynamic Jamming Around a Cylinder Moving Through a Shear Thickening Suspension. OLAV RMCKE, NTNU, Department of Energy- and Process Engineering, IVO R. PETERS, University of Southampton, Faculty of Engineering and Physical Sciences, R. JASON HEARST, NTNU, Department of Energy- and Process Engineering — Dense suspensions exhibit a rich set of behavior, such as shear banding, rheochoa, continuous and discontinuous shear thickening, and in some extreme cases even jamming. Dynamic jamming by shear, which is the focus here, is caused by the formation of a frictional contact network between grains as stress increases. Previous works have shown, in separate experiments, that a transient jammed region can develop under pulling, pushing and shearing. How these different scenarios interact when they appear in a single system, however, is unknown. By dragging a cylinder through a suspension of cornstarch and water, we are able to track the shape of the jammed region as it propagates through the suspension using PIV on the free surface. This work makes it possible to directly compare the propagation of the jammed region, in a system where pulling, pushing and shearing coexist.

4:14PM G04.00003 Flow regimes of a neutrally buoyant suspension in the wake of a circular cylinder\textsuperscript{1}. RAPHAEL MAURIN, MATTHIEU MERCIER, LAURENT LACAZE, Institut de Mécanique des Fluides de Toulouse, Université de Toulouse, CNRS, JEFFREY MORRIS, Levich Institute and Department of Chemical Engineering, City College of the City University of New York — While the rheology of suspensions has been mainly studied in the Stokes regime, fluid mechanical applications such as blood flows or sediment transport at finite particle Reynolds number require a more general understanding. From this perspective, we revisit experimentally the well-known flow around a cylinder, considering a neutrally-buoyant suspension instead of a pure fluid. Varying the particle Reynolds number, \( Re \), and the solid volume fraction, \( \phi \), we investigate various wake structures, from the laminar creeping flow to the Karman vortex street. We characterize the corresponding stability map as a function of \( Re \) and \( \phi \). The presence of particles affects the shape of the wake of the cylinder in a non-trivial way, which cannot be accounted for by a modification of the effective fluid viscosity due to particle loading. Furthermore, the presence of the particles alters the critical values of the Reynolds number at which transitions in the flow regimes occur. These results can also be interpreted by the local behavior of the particles relative to the fluid near specific features of the flow around the cylinder.

4:27PM G04.00004 Fast Lagrangian-averaged transport of particles in streaming flows\textsuperscript{1}. MATHIEU LE PROVOST, JEFF D. ELDREDGE, University of California, Los Angeles — Viscous streaming is an efficient method to transport, trap or cluster inertial particles in a fluid, used in biomecine, microfluidics... Nonetheless, current methods to simulate the long term behavior of inertial particles are computationally expensive due to the nonlinearity and stiffness of the Maxey-Riley equation when applied to the wide disparity of time scales of oscillation and mean convection in streaming flows. To handle these issues, we propose a novel framework called Fast Lagrangian Averaged Transport to efficiently compute the Lagrangian-averaged motion of inertial particles. Two key ingredients are used to get this improved performance. First, we derive an asymptotic expansion for an Eulerian inertial particle velocity field for small Stokes number about the Eulerian fluid particle velocity. Secondly, we decompose the motion of an inertial particle into a mean (slow) and fluctuating (rapid) component derived from an Eulerian disturbance field evaluated at the mean Lagrangian position of the particle. Linearized equations for the disturbance field are derived, and solved using an Immersed Boundary Method. Our method is assessed on the transport generated by one or two weakly oscillating cylinders. Computations are up to 300 times faster with this new method.

\textsuperscript{1}National Science Foundation under grant 1538824
at high Karlovitz numbers. HSU CHEW LEE, PENG DAI, Southern University of Science and Technology, ZHENG CHEN, and is found to be nearly independent of the Reynolds number. Our results are compared with others in the literature.

In this study, we investigate the fractal nature of the surface of several turbulent spherical flames subject to decaying turbulence at varying Reynolds number. We find that the flame surface has a fractal dimension that varies in time, remaining close to 2.4, although the limited size of studies on interfaces in isothermal turbulence, it has been postulated that turbulent flame surfaces exhibit scale-invariant or fractal properties. The flame surface is stretched, folded, and wrinkled on a multitude of length scales ranging from the Kolmogorov scale to the integral scale. Consistently with this study, we investigate the front propagation and burning characteristics in the MILD mode through high-fidelity direct numerical simulation (DNS). As a baseline condition, a lean hydrogen-oxygen mixture at an equivalence ratio of 0.7 is considered, which is diluted with nitrogen.

The turbulence condition falls under the thin reaction zone and high Lewis number. The resulting normalized TKE transport equation involves only a small set of parameters. The Lewis behavior of the terms in the TKE transport equation is analyzed and scaling terms proposed for the thin reaction zone is examined for a broken plane, providing temperature-resolved results and allowing for the study of dispersion as particles travel through the flame. Our results are compared to non-reacting turbulent flows to determine what differences exist between high Karlovitz number flames and non-reacting turbulence. Particular attention is given to recovering Richardson’s scaling and determining how the scaling changes through the flame.

Measurement (Re = 10^4) of a one dimensional lattice of discs in a quasi-two-dimensional geometry with the trajectory of the centres of the disks lying in a plane. We induce initial positional perturbations over a configuration in which the disks are uniformly spaced with their separation vectors and normals aligned, and perpendicular to gravity. For various perturbation wavenumbers and interparticle separations, we find two classes of behaviour: (i) a transient wave of orientations coupled with number-density fluctuations and (ii) a clumping instability resembling that of spheres. J.M. Crowley, J. Fluid. Mech. 45, 151 (1971), decorated with orientations. We construct the equations of motion for displacements and orientations using pairwise addition of forces and torques. R. Chajwa et. al. PRL 122, 224501 (2019). Linear stability analysis demarcates a phase boundary between neutrally stable and unstable regimes in the plane of wavenumber and lattice spacing, consistent with our experiments. We predict non-modal growth in this plane, with a critical density of the lattice below which all wavenumbers are asymptotically stable, showing that orientable particles need not be subject to the inevitable clumping instability of spheres.

Session G05 Turbulent Flames 204 - Peter Hamlington, University of Colorado Boulder
using POD based Finite Time Lyapunov Exponents (FTLEs). SINA RAFATI, University of Texas At Austin, NOEL CLEMENS, University of Texas At Austin — Rare events are defined as the excursions of a dynamical system toward unwanted conditions with possible catastrophic consequences. To that end, the focus of this study is to investigate the interaction of turbulence with a jet flame to better understand the occurrence of rare events in combustion such as flashback, extinction or blowout. Kraichnan (1965) has shown that there is a strong correlation between the existence of rare events and a fluid’s memory. As a consequence, the persistence of an initiated perturbation in a dynamical system for time-scales comparable to the large-scale flow time-scales might lead to rare events. In this study, 20 kHz Particle Image Velocimetry (PIV) has been used for velocity measurement of lifted methane-air turbulent flames. Two Coherent Evolution-90 diode-pumped Nd:YLF lasers were used to create 527nm pulses for PIV. The proper orthogonal decomposition (POD) method was utilized to obtain a compact representation of the velocity field. Then, the high-dimensional velocity field was projected into a lower-dimensional space for Lower Order Reconstruction (LOR) of the flow field with the aim of bringing new insight to the contribution of various scales in the chaotic development of the flow. Finally, Lagrangian coherent structures (LCSs) are obtained as ridges of FTLE maps to study the flow topologies as a function of space and time. Our results are representing how LCSs interact with flame as they are approaching to the flame front.

**4:53PM G05.00006 Compressive Dynamics of Fast Turbulent Flames**

RACHEL HYTIVOVC, JONATHAN SOSA, JESSICA CHAMBERS, KAREEM AHMED, ALEXEI POLUDNENKO, VADIM GAMEZO, None — h — abstract —

The research characterizes the dynamics of compressible flame-turbulence interactions for propagating fast flames. A Turbulent Shock Tube with a series of turbulence inducing plates has a large viewing area to capture the flame dynamics with various optical diagnostics, including high-speed PIV and schlieren. The experimental results show that the turbulent Mach number, $M_f$, within the flame increases non-linearly relative to the flame propagation Mach number, $M_f$, and grows quickly for flames propagating faster than Chapman-Jouguet deflagrations ($M_f > 1$). This relationship shows that turbulence is self-generated by fast turbulent flames. Furthermore, the flames with $M_f > 1$ are intrinsically unsteady. They tend to accelerate and generate shocks. This acceleration is accompanied by the fast increase of $M_f$ and continues until shocks become strong enough to ignite a detonation. Slower flames with $M_f < 1$ show, little or no self-generated turbulence, and do not produce shocks. The results are highly relevant for hypersonic scramjet propulsion engines and compressible shock-laden turbulent reacting flows in rotating detonation engines.\[2/-abstract-

**5:06PM G05.00007 Kinetic Energy Backscatter in High-Speed, Compressible Reacting Turbulence**

ARNAB MOITRO, ASHWATH SETHU VENKATARAMAN, ALEXEI POLUDNENKO, Texas A&M University — Previous studies have shown that in certain reacting flow regimes, near the flame region, the direction of kinetic energy cascade reverses compared to the non-reacting turbulence, and is primarily directed from small scales to large scales on average. Studying this phenomenon (often termed backscatter) is important for developing large-eddy simulation (LES) models for turbulent combustion. Previous studies, however, were limited to relatively low-Mach number flows in idealized geometries. In the present work, we study the backscatter in highly-compressible regimes characterized by large Reynolds numbers. In particular, we present direct numerical simulations (DNS) of the flow in a Turbulent Shock Tube facility designed at the University of Central Florida with the goal of probing the dynamics of turbulent flames in such fast regimes. We quantify the backscatter by low-pass filtering the primitive variables in the DNS at various scales, and evaluating the the sub-filter scale terms in the equation for the transport of kinetic energy. Finally, we discuss the implications of these results for the development of the new generation of LES models for high-speed, compressible reacting flows.

**5:19PM G05.00008 Direct Numerical Simulation of Flame-Wall Interaction in a Constant Volume Vessel with a Crevice**

YUKI MINAMOTO, Tokyo Institute of Technology, ANDREA GRUBER, SINTEF Energy Research, MAMORU TANAHASHI, Tokyo Institute of Technology — Understanding of flame-wall interaction phenomena is important for further reduction of pollutant formation and enhancement of efficiency of various combustors. Many combustion devices involve crevice regions which yields much smaller length scale than the size of a combustor. In such crevice regions, the wall heat loss and turbulent mixing could be modified due to the geometrical effect of the crevice, resulting in more complex flame-wall interaction, which is not fully understood. In this study, a DNS of turbulent methane-air flame-wall interaction in a constant volume vessel with a crevice has been performed to understand the combustion physics near the crevice region. The present DNS configuration is chosen based on a typical IC engine combustion in terms of domain and crevice sizes and turbulent combustion condition on the combustion diagram, although methane-air combustion at atmospheric pressure was considered. The visual examination of DNS results shows that the mixture in the main domain is entrained and mixed with the mixture in the crevice. On the other hand, the mixture in the crevice is cooled as thermal boundary layer develops. The DNS results also revealed several interesting thermochemical and fluid dynamic aspects relevant to near-wall crevice combustion.

**3:48PM G06.00001 Modelling peak supersonic heated jet noise at fixed jet or fixed acoustic Mach number using an acoustic analogy-based non-parallel flow asymptotic approach**

MOHAMMED AFSAF, University of Strathclyde, ADRIAN SESCUC, Mississippi State University, EDMONDO MINISCI, University of Strathclyde — This presentation provides a summary of our recent results on supersonic jet noise prediction using the generalized acoustic analogy approach. The analogy poses a formula for the far-field sound as a convolution product of propagator tensor and the fluctuating Reynolds stress auto-covariance tensor. We found that approximating the propagator tensor using a non-parallel flow asymptotic approximation (AfSar et al., 2019. Phil. Trans. A, in press) of the vector Green’s function that satisfies the adjoint linearized Euler equations allows accurate prediction of the peak jet noise. That is, in the small observation angle region, the predictions remain within 1-2 dB of experimental data up to a Strouhal number (based on jet diameter) of at least 0.5. We base the analogy on a model of the Reynolds stress auto-covariance that agrees with Large-Eddy Simulations in isothermal conditions. In general, our predictions recover both the spectral quietening observed in heated jets at fixed acoustic Mach number (AfSar et al. AIAA J., vol.49, p.2522, 2011) and the noise enhancement at fixed jet Mach number. We observed that in either of these cases, using the simpler non-spreading locally parallel flow based Greens function results in a significant under prediction of sound.
4:01PM G06.00002 Large eddy simulations of supersonic twin rectangular jets including screech\textsuperscript{1}. JINAH JEUN, GAO JUN WU, SANJIVA K LELE, Stanford University — In this work the aeroacoustics of supersonic jets including screech tones, issuing from military-type twin rectangular nozzles with aspect ratio of 2.1 and design Mach number of 1.5, is studied numerically. Large eddy simulations (LES) are performed using the unstructured compressible flow solver ChalLES developed by Cascade Technologies, to fully replicate the nozzle geometry including the upstream duct with flow divider and sharply turning converging-diverging nozzle. Equilibrium wall-model is used to account for the internal boundary layers. Three different nozzle operating conditions, which correspond to two over-expanded conditions and one ideally-expanded condition, are considered. At each operating condition, the far-field acoustic spectra are obtained from the near-field LES data and the far-field flow statistics and the far-field acoustic modes are compared with experiments conducted at the University of Cincinnati, to examine predictive capabilities of the LES solver. Interactions between closely placed two jet plumes as they spared are captured, and the effects of nozzle operating conditions on them are discussed.

\textsuperscript{1}This work was supported by the Office of Naval Research under Grant No. N00014-18-1-2391.

4:14PM G06.00003 Sound Sources in Subsonic Twin Turbulent Jets, ARNAB SAMANTA, NISHANTH MUTHICHUR, SANTOSH HEMCHANDRA, Indian Institute of Science — We analyse the sound from merging identical twin jet plumes. The far-field acoustic spectra are obtained using the near-field LES data and the far-field flow statistics and the far-field acoustic modes are compared with experiments conducted at the University of Cincinnati, to examine predictive capabilities of the LES solver. Interactions between closely placed two jet plumes as they spared are captured, and the effects of nozzle operating conditions on them are discussed.

4:27PM G06.00004 Wavenumber-frequency spectra of wall-pressure fluctuations in compressible turbulent channel flow\textsuperscript{1}. YI LIU, KAN WANG, MENG WANG, University of Notre Dame — Knowledge of wall pressure fluctuations in wall-bounded flows is important for predictions of structural vibration and noise. In this study, direct numerical simulations with a high-order, non-dissipative finite difference scheme are employed to accurately capture the spatiotemporal characteristics of wall pressure fluctuations in compressible turbulent channel flows at Mach 0.4 and friction Reynolds number of 180. Acoustic peaks are barely visible in the one-dimensional streamwise wavenumber-frequency spectra. However, in the two-dimensional wavenumber-frequency spectra at the zero spanwise wavenumber, acoustic peaks associated with both longitudinal and oblique propagating waves are clearly identifiable, although they are several orders of magnitude weaker than the convective peak. The number of oblique-wave peaks at each frequency matches the theoretical prediction for duct acoustic modes. The effect of a small two-dimensional hump on the channel surface is also investigated. The results suggest that acoustic scattering by the hump vastly increases the acoustic energy for both longitudinal and oblique modes.

4:40PM G06.00005 Analysis of Screech Generation in a Cold Supersonic Rectangular Jet with Large-Eddy Simulations\textsuperscript{1}. GAO JUN WU, Department of Aeronautics and Astronautics, Stanford University, SANJIVA LELE, Department of Aeronautics and Astronautics and Department of Mechanical Engineering, Stanford University, JINAH JEUN, Center for Turbulence Research, Stanford University — Screech is an aeroacoustic phenomenon found in non-ideally expanded supersonic jets. Using large-eddy simulations, this work studies screech generation for a cold under-expanded rectangular jet at several Nozzle Pressure Ratios (NPRs) around maximum screech. The aspect ratio of the converging-diverging rectangular nozzle is 4:1 and the design Mach number is 1.44. In the noise spectra, screech tones are observed at near-field locations. Spectral Proper Orthogonal Decomposition (SPOD) techniques are used to extract the temporal-spatial coherent structures from the LES data. At the screech frequency, a flapping motion is detected along the minor-axis plane, and a spatially modulating antisymmetric standing wave pattern is observed in the near field as a result of oppositely travelling hydrodynamic and acoustic wave packets. In contrast to the conventional belief that screech feedback is closed by upstream-travelling acoustic waves outside the jet, recent research has indicated that the closure mechanism could arise from an internal acoustic mode supported by jet plumes. To further investigate this hypothesis, a linear instability analysis for the jet flow will be conducted, and the results will be compared with the SPOD data.

\textsuperscript{1}This work is supported by ONR Grant No. N00014-18-1-2391. Computational resources are provided by the INCITE and XSEDE programs.

4:53PM G06.00006 Linear stability analysis of supersonic jet screech. MICHAEL KARP, TIM FLINT, M. J. PHILIPP HACK, Center for Turbulence Research, Stanford University — Jet screech is an undesirable flow phenomenon which can pose severe limitations on the operation of jet engines. Screech is commonly understood as a feedback cycle involving interactions between instability waves, shear layers, shocks and acoustic waves. Our study seeks to advance the insight into the physics of jet screech by means of global linear stability theory. We consider steady laminar axisymmetric jets at supersonic conditions. Both under-expanded and perfectly expanded jets are investigated at various exit Mach numbers. The analysis connects the occurrence of screech to an absolute instability of the under-expanded jet. The features of the eigenmodes are discussed and their relevance to the elements of the screech cycle is explored. An adjoint analysis quantifies the receptivity of jet screech to internal and external perturbations.

5:06PM G06.00007 A New Instance of Crackle Noise. JOSEPH MATHEW, SUMIT PATEL, Indian Institute of Science — Intense crackle noise has been identified and studied in high temperature, supersonic jets of engines operating at high specific thrust. We observed a new instance of crackle noise in cold under-expanded supersonic jets (Mach 1.5, Reynolds number 100,000) impinging on plane wedges. LES is by explicit filtering, with a new adaptive filtering method for shock capturing. Crackle fronts appear when a detached normal shock stands about half a jet-width from the wedge tip, and the jet column is about 4 jet-widths (nozzle to wedge tip). The edges of these oscillating shock interact with the jet’s bounding shear layer structures to emit acoustic wave fronts that steepen as they travel into the far field. Pressure signals exhibit sudden rises followed by gentle relaxations, intermittently. Consistently, pressure distributions along lines in the ambient show the existence and arrival of a sequence of sharp compression fronts. Skewness exceeds 0.4 in the far field. Crackle fronts do not appear in other configurations such as a short column (steady shock), short column and thin wedge (steady, attached, oblique shock), and a long column, thin wedge (large amplitude column oscillations).
Approach provides a 3D map of the residence time, while the latter estimates the order of magnitude. Circulation in a plane normal to the axis of the vortex dominating the aneurysm sac is used to estimate the eddy turnover time. The former approach provides a 3D map of the residence time, while the latter estimates the order of magnitude. In the Eulerian approach, risk of rupture in untreated aneurysms and risk of thrombo-embolism in treated aneurysms. In this study, we use in vitro 4D MRI velocimetry to model blood flow in aneurysms.

Additional clinical observations indicate thrombus formation following aneurysm endovascular treatment perhaps due to inadequate blood flow. It is well known that blood flow residence times of critical stenoses significantly influence the formation of thrombosis and the risk of rupture. Blood flow residence times are not fully understood, and there is emerging evidence that blood flow residence times are associated with the formation of thrombosis in cerebral aneurysms.

The carotid phantom was constructed with a 3D printer based on the CT image of patient and the actual pulsatile flow. To reproduce the patient's blood flow measured by US Doppler probe. The blood mimicking glycerin aqueous solution was used as a working fluid. The overall experimental setup was designed to reproduce the patient's blood flow measured by US Doppler probe. The blood mimicking glycerin aqueous solution was used as a working fluid.

The carotid phantom was constructed with a 3D printer based on the CT image of patient and the actual pulsatile flow. To synchronize the pulsatile flow, a digital pulse was transmitted to the MR scanner as trigger when the wave form started. As a result, a time-resolved 3D pulsatile flow with a high spatiotemporal resolution (350 um iso and 25 ms) was obtained.

Assessment of cardiac output effects on bioprosthetic pulmonary valve behavior using magnetic resonance velocimetry. The geometry-independency of the estimation of turbulence production and corresponding irreversible pressure drop was demonstrated and quantified. The flow configurations are investigated where scattering of boundary layer instabilities lead to tonal noise generation including equidistant secondary tones. Despite the geometric symmetry at zero deg. incidence, the flows become non-symmetric with a separation bubble on one side of the airfoil. A separation bubble is also observed for the non-zero incidence flow. It is shown that the frequency motion of the separation bubbles induces a frequency modulation of flow instabilities developed along the airfoil boundary layer. The airfoil is at zero deg. angle of attack, and the flow quantities result in a complex vortex interaction mechanism at the trailing edge. Both amplitude and frequency modulations directly affect the velocity and pressure fluctuations that are scattered at the trailing edge, what leads to secondary tones in the acoustic radiation.

Assessment of Reynolds stress using 4D Flow MRI for estimating the irreversible pressure drop across a stenosis. This study demonstrates novel geometry-independency of the irreversible pressure drop across stenoses by quantifying the amount of turbulence production. Based on 4D Flow MRI-based assessment of turbulence mapping using a six-directional icosahedral (ICOSA6) flow encoding scheme for measuring the complete Reynolds stress tensor, the feasibility of 4D Flow MRI for the quantification of irreversible pressure loss was investigated in a range of voxel sizes and signal-to-noise ratios (SNR) by simulating 4D Flow MRI based on data from computational fluid dynamics (CFD). The geometry-independency of the estimation of turbulence production and corresponding irreversible pressure drop was investigated using several stenoses. Finally, experimental acquisitions using 4D Flow MRI with ICOSA6 flow encoding were used to demonstrate the assessment of the irreversible pressure drop.

MRI-based flow residence time in intracranial aneurysms. The mechanisms behind development of thrombosis in cerebral aneurysms is not fully understood, and there has been emerging evidence that blood flow residence time is correlated/associated with the lesion. In addition, there have been clinical observations indicating thrombus formation following aneurysm endovascular treatment perhaps due to altered hemodynamics. Therefore, a characterization of the residence time can play an important role in the development of a biomarker for the risk of rupture in untreated aneurysms and risk of thrombo-embolism in treated aneurysms. In this study, we use in vitro 4D MRI velocimetry for several aneurysms performed in a 3 Tesla magnet at submillimeter resolution to compute the flow residence time using both Lagrangian and Eulerian frameworks. As per our previous study, by integration of the volumetric velocity field, Lagrangian tracks of massless tracers are computed, followed by the residence time calculation using the presence of fluid parcels in a local and global sense. In the Eulerian approach, circulation in a plane normal to the axis of the vortex dominating the aneurysm sac is used to estimate the eddy turnover time. The former approach provides a 3D map of the residence time, while the latter estimates the order of magnitude.
Remarkably, the extracted droplet is automatically and firmly trapped in the sound field which acts as an acoustic tweezer. High speed video was taken to display the dynamics of the interface during the procedure when the interface was broken deforming it against the incident direction of the sound beam. The direction of this force depends on the relative sound speeds and densities of the two fluids. We demonstrate the extreme case where a properly designed ultrasonic beam is used to break the interface and extract a single droplet from an interface of water to CCl$_4$. The experiment was repeated with a range of ultrasonic frequencies to study the effect on the droplet extraction process.

Ultrasonic extraction and trapping of a droplet from fluid-fluid interfaces.

Robert Lirette, Likun Zhang, Joel Mobley, The University of Mississippi — Ultrasonic waves provide a powerful means to exert forces on fluid objects (droplets and fluid interfaces) for the development of non-contact manipulation techniques or acoustic tweezers. Under proper conditions, a high-frequency sound wave can exert a pulling force on the interface of two immiscible fluids causing it to deform against the incident direction of the sound beam. The directional control of this force depends on several factors including the sound speed and density of the two fluids. This study demonstrates the feasibility and potential applications of this technique for the non-invasive manipulation of fluid interfaces.
4:01PM G08.00002 Capillary surfers: Self-propelling particles at an oscillating fluid interface1, GIUSEPPE PUCCI. Brown University and Institute of Physics of Rennes, DANIEL HARRIS, Brown University — In the present work, we explore the dynamics of millimeter bodies trapped at the air-water interface of an oscillating bath. The relative vertical motion of the body and the free surface leads to the generation of propagating capillary waves. We demonstrate that when the rotational symmetry of an individual particle is broken, the particle can steadily self-propel along the interface. Such self-propelled particles interact with one another through their mutual capillary wavefield and resultant fluid flows, and exhibit a rich set of collective modes characterized by a discrete number of equilibrium spacings for a given set of experimental parameters. Our results open the door to further investigations of this novel active system at the fluid interface. Ongoing work and future directions will be discussed.

1G. Pucci thanks the program CNRS Momentum for its support.

4:14PM G08.00003 Collective dynamics of dense particles at a liquid interface, ANTOINE LAGARDE, Institut Jean Le Rond D’Alembert, Sorbonne Universite, CHRISTOPHE JOSSERAND, LadHyX, Ecole Polytechnique, SUZIE PROTIERE, Institut Jean Le Rond D’Alembert, Sorbonne Universite — When two millimeter-sized identical objects are deposited at a liquid interface, the individual deformations they create may overlap, leading to an attractive capillary force. This everyday phenomenon that one can observe at the surface of water is central in many applications, from industrial processes where it is used to manufacture objects with a specific microstructure to Nature where fire ants gather into a raft to survive floods. The interaction between two identical spherical particles is now rather well understood, but the many-body interaction of non-identical aggregates still lacks a convincing description. Here, we experimentally study the aggregation of randomly distributed dense millimeter-sized beads placed at an oil-water interface. The particles are attracted by their neighbors and form an asymmetric mound called a granular raft. The interfacial deformation created by such an object exceeds by at least one order of magnitude the deformation of a single bead, leading to high capillary forces that strongly depend on the number of particles in each raft. Thanks to a precise understanding of the interaction between two rafts, we undertake a statistical description of the aggregation process of a n-body system into a single giant granular raft.

4:27PM G08.00004 Low-G inertial-capillary meniscus motions in a channel1, JOSH MCCCRANEY, PAUL STEEN, Cornell University, JOSHUA BOSTWICK, Clemson University — In low-g environments, residual accelerations can induce fluid reservoir reconfiguration, resulting in dynamic instabilities. Since channel geometries are prevalent aboard critical spacecraft fluid systems, such as propellants, cryogens, and wastes, understanding flow stability is crucial to ensure fluid is positioned and available when needed. In this work we analyze the normal oscillations of a low-g fluid in a rectangular channel, reporting fundamental frequencies for pinned, natural, and mobile contact line conditions.

1NASA Grant NNH17ZTT001N- 17PSI D

4:40PM G08.00005 Capillary Sorng of Particles by Dip Coating , BRIAN DINCAU, University of California Santa Barbara, MARTIN BAZANT, Massachusetts Institute of Technology, EMILIE DRESSAIRE, ALBAN SAURET, University of California Santa Barbara — High-throughput sorting or filtration of suspensions is a critical step in many industrial, geophysical, and biomedical processes. Here, we present a new scalable size-based separation technique which utilizes a dip coating meniscus as a tunable filter. When a plate is withdrawn from a liquid bath, a thin layer of liquid coats its surface. Below a given film thickness on the plate, the meniscus generates a strong capillary force at the stagnation point and prevents large particles from being entrained in the liquid film. We leverage the capillary filtration effect induced by the meniscus to sort particles by size. Indeed, the size threshold depends on the withdraw speed and fluid properties, so smaller particles are entrained while larger particles remain in the bath. We demonstrate this technique with bidisperse suspensions and explain how it could be applied to polydispersed suspensions or extended to biological suspensions. We rationalize our results in terms of dimensionless numbers (capillary and Bond numbers) and estimate the range of capillary number to separate particles of given sizes. This technique is well-suited for high-throughput operation due to the demonstrated scalability of industrial dip coating, combined with the clog-free nature of this meniscus-based filter.

4:53PM G08.00006 Steady Buckling of Viscous Capillary Jets , NEIL RIBE, CNRS, University Paris-Saclay, Orsay, France, JINGXUAN TIAN, XIAOXIAO WU, ANDERSON SHUM, Dept. of Mechanical Engineering, University of Hong Kong — Steady buckling (coiling) of thin falling liquid jets plays an important role in instability-assisted high-resolution printing and ultra-fine liquid dispensing, situations in which the effects of surface tension are likely to be significant. To understand better these capillary effects, we have performed experiments with sub-millimetric jets and ultra-low flow rates (∼10 ml/h) together with numerical simulations and linear stability analysis to study a hitherto unexplored reconfiguration dominated by capillarity with negligible inertia. We find that the critical fall height $H_c$ for coiling onset decreases with increasing flow rate, a tendency that is opposite to the zero surface-tension case and that has been previously documented only for inertia-dominated coiling. The enhanced resistance to buckling afforded by surface tension increases $H_c$ by up to a factor of 10 relative to the surface tension-free case. A regime diagram in the space of capillary number and jet slenderness agrees closely with the prediction of the linear stability analysis, but differs significantly from the analogous diagram for unsteady buckling of a compressed liquid bridge constructed previously by other workers.

5:06PM G08.00007 The Dynamics of Curved Thin Films Under Soluto-Capillary Forces , XINGYI SHI, MARIANA RODRIGUEZ-HAKIM, GERALD FULLER, ERIC SHAQFEH, Stanford University — Interfacial film dynamics is ubiquitous and is interesting in the presence of bulk and/or interfacial heterogeneity. To control the stability of thin films over different substrates, we need a fundamental understanding of the physical forces that affect the film, particularly when the film is heterogeneous. In the present study, we examine the thin film dynamics of a binary mixture subject to evaporation and drainage atop both a glass dome and an air bubble. Experimentally, we observe the film thickness profiles via a custom-made dynamic fluid-film interferometer. In the parallel computer simulations, we develop a lubrication theory to compute the film thickness evolution under the effects of capillarity, gravity, Marangoni forces, and van der Waals interactions with the substrate. We find the dynamics are quite complex and subject to long-lived time dependent states thus soluto-capillary forces stabilize the film. Moreover, we find that stabilizing van der Waals forces are crucial to create the conditions for Marangoni regeneration for drainage over a solid substrate. For a draining, heterogeneous thin film over a bubble surface, we find sustained, nonlinear thickness oscillations are rather easily accessible.
The finite-time Lyapunov exponent (FTLE) was used to analyze the unsteady flow around a pitching NACA 0012 airfoil. Wake characteristics (i.e., vortex size, peak vorticity, vortex orientation, vortex convection speed) are investigated by tracking the airfoil. The airfoil is pitched about the quarter chord point with an amplitude of $4\alpha$ at reduced frequencies of 2.6-5.8 for $Re_c = 12000$. Pitching symmetries of 50/50, 60/40, and 70/30, where the symmetry is defined as the fraction of the cycle spent in the pitch down and pitch up motion. Wake characteristics (i.e., vortex size, peak vorticity, vortex orientation, vortex convection speed) are investigated by tracking the vortices in the wake over the first chord length of development. Mean thrust/drag are calculated using a control volume approach including fluctuating terms.

This work was supported by the Office of Naval Research under ONR Award No. N00014-14-1-0418.
4:40PM G09.00005 Effect of Chordwise Flexibility on Propulsive Performance of High-Inertia Oscillating Foils1. PETER OSHKAI, DYLAN IVerson, MOSTAfA RAHMIPOUR, WALTFRDeE LEe, University of Victoria, TAKAHIRO KIWATA, Kanazawa University — This work studies the effects of chordwise flexibility, inertia and kinematic parameters on propulsive performance of an oscillating foil. Three low-aspect-ratio foils with different flexibilities were undergoing pitch and heave motions in a uniform flow at the Reynolds number of 80000. Forces exerted on the foil were directly measured using a load cell and were used to calculate the thrust and efficiency values. The phase-averaged flow velocity and out-of-plane vorticity in the wake of the foil were obtained using particle image velocimetry. The circulation in the wake was related to the loading on the foil by calculating the moments of vorticity with respect to the pitching axis of the foil. The generated thrust values monotonically increased as a function of the Strouhal number for the considered range of pitching angles. The deformation of the foil resulted in an increased wake width, leading to larger amplitudes of the instantaneous loading on the foil and higher thrust coefficient compared to a reference case of a rigid foil.

4:53PM G09.00006 Vortex dynamics of a rapidly pitching elliptical airfoil exhibiting dynamic stall at low Reynolds numbers. JOHN HRYNUK, US Army Research Lab, MINGJUN WEI, Kansas State University — The flow features and effects of dynamic stall have been traditionally studied for rotorcraft and in small bio-flyers. In rotorcraft focused dynamic stall studies a sinusoidal pitching motion is commonly used, while a perching maneuver for small vehicles is better represented by a constant pitch-and-hold motion. For pitch-and-hold motions the interaction of Dynamic Stall Vortex (DSV) and Trailing Edge Vortex (TEV) appear to have a significant impact on vortex circulation and convection. To expand the understanding of the interaction of DSV, TEV, and basic vortex shedding phenomenon, an elliptical airfoil shape was pitched about mid-chord with a constant dimensionless pitch rate. Flow fields were captured using PIV at a Reynolds number of Re = 12,000. Results show that depending on the phase angle of the airfoil, the flow is dominated by the DSV, TEV, or traditional bluff body shedding. These regions of phase angle will be delineated and vortex tracking methods will be used to evaluate convection behavior of the trackable structures.

5:06PM G09.00007 Dynamic stall experiments on various pitching motion profiles of an airfoil at high Reynolds numbers. JANIK KIEFER, Technical University of Denmark, CLAUDIA BRUNNER, MARCUS HULTMARK, Princeton University, MARTIN O. L. HANSEN, Technical University of Denmark — The combination of high Reynolds numbers and unsteady flow conditions depicts a challenge in experimental wind tunnel studies. Unsteady airfoil aerodynamics are commonly described by the reduced frequency k = omega c/2U, where a range of 0 < k < 0.25 characterizes steady to highly unsteady flow conditions. The Reynolds number scales proportionally with the flow velocity U, whereas the reduced frequency scales inversely proportional. In regular wind tunnels, this leads to unrealistically high pitching frequencies in experimental attempts to achieve high Reynolds numbers simultaneously with high reduced frequencies. Instead, this study takes advantage of a high-pressure flow facility, in which the density of compressed air promotes high Reynolds numbers, while low velocities below 5 m/s allow for low pitching frequencies and large angle amplitudes. A NACA0021 airfoil was equipped with surface pressure sensors to investigate distributed pressures and integrated forces at Reynolds numbers between one and five million. The present study elucidates the differences of various motion profiles on airfoil performance in comparison to the commonly employed sinusoidal pitching motion in dynamic stall conditions.

5:19PM G09.00008 Dynamic Stall Experiments on a Sinusoidally Pitching Airfoil at High Reynolds Numbers1. CLAUDIA BRUNNER, Princeton University, JANIK KIEFER, Technical University of Denmark, Princeton University, MARTIN O. L. HANSEN, Technical University of Denmark, MARCUS HULTMARK, Princeton University — The phenomenon of dynamic stall results in a lift overshoot experienced by an airfoil when its angle of attack is rapidly increased beyond the static stall angle. This overshoot is followed by a sudden drop in the lift force, and large hysteresis as the airfoil returns to its initial angle. Dynamic stall is observed in a variety of applications including helicopters and wind turbines, where it produces rapidly fluctuating loads on the blades. It is also seen in many biological systems, but they often use it advantageously. At low and moderate Reynolds numbers and reduced frequencies, this phenomenon has been extensively investigated, but due to the experimental challenges at high Reynolds numbers, only few studies have been conducted in this regime. In the current study, a NACA 0021 airfoil was oscillated sinusoidally around the static stall angle. A highly pressurized, low-velocity, wind tunnel was used to achieve Reynolds numbers up to 5 - 106, based on the chord length, and reduced frequencies up to 0.5. Forces and moments on the airfoil, as well as pressure distributions around its surface were recorded. Effects of Reynolds number, reduced frequency, mean angle of attack, and amplitude on the development of dynamic stall will be presented.

3:48PM G10.00001 Effect of sweep on the laminar separated flows over finite-aspect-ratio wings1. KAI ZHANG, KUNIHKO TAIRA, University of California, Los Angeles — Separated flows over finite-aspect-ratio wings at low Reynolds numbers can exhibit rich wake dynamics across a range of aspect ratio, angles of attack, and sweep angles. In this talk, we focus on the effect of sweep on the three-dimensional flow physics behind finite NACA0015 wings. The post-stall wake of an unswept finite wing features a prominent tip vortex at the free end and unsteady wake vortices near the midspan. For a swept wing, a steady wake region forms from the midspan and the unsteady shedding region repositions toward the tip. The sweep-induced spanwise flow counteracts the roll-up of the flow over the wing tip, hindering the formation of the tip vortex. Corresponding to the spanwise variation of the vortical structures, the sectional lift coefficient is largest at the midspan, and decreases towards the wing tip. At large sweep angles, the wake of finite wings exhibits streaks of steady streamwise vortices that are embedded in the spanwise-undulated vortex sheets. In this talk, we discuss findings from a large parametric study and offer comparisons with wake behind unswept wings.

4:01PM G10.00002 Effect of boundary conditions on 3-D separation over an airfoil. SHELBY HAYOSTEK, MICHAEL AMITAY, Rensselaer Polytechnic Institute — Boundary conditions greatly affect the wake topology around a finite-span, low aspect ratio airfoil. Two sets of boundary conditions were imposed on the airfoil and their effect was explored in water tunnel experiments. First, the model was cantilevered from a wall where the thickness of the boundary layer, at the junction between the airfoil and the wall, was about half the airfoils span. The second model was with two free ends, where the model was held by a thin rod attached to the wall. In both cases, the airfoils had a NACA 0015 profile with an aspect ratio of 2, and were tested at a range of angles of attack and chord Reynolds numbers of 600 and 1,000. In addition, the airfoils were either unswept or 30 degrees swept back. Stereo particle image velocimetry and dye flow visualization were used to capture the flow field. It was found that for the unswept case, the boundary layer greatly affected the flow structures in the wake, with a dual vortex system forming at the tip. However, for the sweep case, the spanwise velocity component pushed the wake towards the tip and the effect of the boundary condition was smaller compared to the unswept cases.

4:14PM G10.00003 Three-dimensional separation over a finite span NACA 0015 airfoil. JACOB NEAL, MICHAEL AMITAY, Rensselaer Polytechnic Institute — Three-dimensional separation over a finite span, cantilevered NACA 0015 airfoil is influenced by several parameters. The effects of aspect ratio, Reynolds number, and angle of attack were explored in a series of wind tunnel experiments. Oil flow visualization (OFV) was performed on wings of aspect ratio four, two, and one. For all aspect ratios, it was seen that the Reynolds number did not affect the structures in the oil. For angles of attack above stall, two distinct foci were formed, one near the root and another counter-rotating near the wing tip. In addition, for a couple of cases, the flow field over the airfoil and the structures in its wake were explored using stereo particle image velocimetry at Reynolds number 330,000 for aspect ratio of two. At the higher angle, a clear three-dimensional separation bubble was present at the middle of the wing, and a surface normal vortex was seen to emerge from the focus points seen in the OFV and bend downstream into the flow.

4:27PM G10.00004 Dynamic stall and its post-stall lift decay1. SABRINA HENNE, KAREN MULLENERS, EPFL — Dynamic stall occurs when an airfoil undergoes dynamic changes in the angle of attack beyond its static stall angle. It can be observed for example on helicopter or wind turbine blades. Dynamic stall is associated with an increase in maximum lift, but this initial peak is followed by strong load fluctuations. These fluctuations can cause vibrations, structural damage, and failure. To identify the origin of the decay of post-stall lift fluctuations, the flow around a flat plate undergoing a ramp-up motion from an angle of attack of zero to an angle beyond the static stall limit was investigated using time-resolved flow field and load measurements. Immediately following the ramp-up motion, multiple subsequently shed leading edge vortices are observed and their separation coincides with local maxima in lift. The magnitude of these local lift maxima decays in time. A detailed analysis of the size and trajectory of the dominant leading edge vortices using Eulerian and Lagrangian methods helped to characterise the decay of post-stall lift peaks and quantify the importance of variations in the development of the leading edge vortices and changes in the wake topology on the airfoil’s post-stall performance.

4:40PM G10.00005 Time-Resolved PIV Airwake Measurements of a Frigate Ship Model1. ZHENG ZHANG, DHUREE SETH, EBENEZER GNANAMANICKAM, GORDON LEISHMAN, Embry-Riddle Aeronautical University, Daytona Beach, FL — The full ship model with standard Navy SFS2 geometry was tested in a 6 ft (W) by 4 ft (H) by 12 ft (L), closed circuit, low-speed wind tunnel. A time-resolved planar PIV system was used to measure the temporal flow field at the centerline of the deck behind the funnel and hangar structures. The measurements were conducted at Reynolds numbers up to 8 million based on the length of the ship model. The flow field was noted to be dominated by two major structures, namely the wake of the funnel and the shear layer emanating from the superstructure of the ship and top of the hangar. The reattachment behind the hangar structure induced the shear layer reattach to the surface at approximately the middle of the deck, resulting in a highly energetic turbulent flow close to the surface. Dynamic model decomposition of the time-resolved flow field revealed existence of multiple dominant frequencies, indicating complex vortex flows in the vicinity of the deck. The ship model was also tested in a simulated atmospheric boundary layer, the results suggesting that the associated velocity gradient and higher turbulence weakens the shear layers produced over and near the deck.

4:53PM G10.00006 Effects of spanwise inhomogeneity on wake dynamics of a cylinder1. CHAO JIANG, YEFEI YANG, SHUJIN LAIMA, HUI LI, Harbin Institute of Technology — The flow over a twisted cylinder at low Reynolds numbers of Re=30-300 is investigated using direct numerical simulation based on the finite volume method. The elliptic cross-section of the cylinder is rotated along its axial direction, thus resulting in inhomogeneity of the geometry. For comparison, the flow past a smooth and a wavy cylinder is also calculated. The twisted cylinder achieves reductions of approximately 90% both in mean drag and lift fluctuation compared with smooth and wavy cylinders. When Re>160, the time trace of drag and lift for the twisted cylinder reveals the presence of multi-frequency oscillations, which is different from the other two. The plot of Strouhal number vs. Reynolds number for the twisted cylinder strikingly exhibits four discontinuities, while only two for the smooth cylinder. The first discontinuity corresponding to the start point for transition of the flow, moves towards a lower critical Reynolds number.

5:06PM G10.00007 Boundary Layer Separation from Sports Balls with Seams. ANDREW SMITH1, BARTON SMITH2. Utah State University — Results of a study on the behavior of boundary layer separation of various sports balls with seams using particle image velocimetry (PIV) is presented. Our primary focus is the boundary layer state at separation, the location of separation, and the angle formed by the separated shear layer. The study uses moving balls in free space rather than a wind tunnel, which may alter critical pressure gradients and affect separation behavior. The bulk of the results presented will be for non-rotating major league baseballs. The seams on baseballs play two distinct roles: 1) the may cause the laminar boundary layer to become turbulent (when located on the front of the ball) and 2) they often form the separation location (when on the back of the ball). The effect of surface roughness (scuffs) on boundary layer separation is also studied. To better understand the effects of seams, other seamless sports balls are examined including a cricket ball, a smooth ball, a sliotar (hurling ball), an artificially roughened leather baseball, and a printed baseball with exaggerated seams.
5:19PM G10.00008 Separating and reattaching turbulent boundary layer due to an unsteady adverse pressure gradient

JUNSHIN PARK, DONGHYUN YOO, Pohang University of Science and Technology — Turbulent boundary layer subject to an unsteady adverse pressure gradient (APG) is studied using direct numerical simulation (DNS). The unsteady APG is imposed with a suction/blowing velocity profile at the top numerical boundary to evoke boundary layer separation and reattachment. In particular, the suction/blowing velocity profile is varied sinusoidally in time at several different reduced frequencies: \( k = 0.75, 0.75 \) and \( 0.25 \). Results have shown that for reduced frequencies \( k = 0.75 \) and \( 0.25 \), flow features differ greatly from those of separated flow with a steady APG. The separated shear layer lifts up at the first half-period of the APG oscillation. Flow near the reattachment region is entrained back inside the separation bubble. Large vortices are subsequently generated and convect downstream while the separated shear layer leans down to the wall at the latter half-period of the APG oscillation. Differences in time-averaged turbulent kinetic energy are also observed compared with the steady counterpart. To investigate the origin of such differences between flows with steady and unsteady APG, dynamic mode decomposition is also applied. Identified dynamic modes show features related to the aforementioned unsteady behavior.

3:48PM G11.00001 Molecular Tagging Velocimetry Study of High Reynolds Number Turbulent Pipe Flow in Cryogenic Helium, HAMID SANAVANDI, Department of Mechanical Engineering, Florida State University, Tallahassee, Florida, SHIRAN BAO, National High Magnetic Field Laboratory, Tallahassee, Florida, YANG ZHANG, Florida Center for Advanced Aero-Propulsion, Tallahassee, Florida, WEI GUO, National High Magnetic Field Laboratory, Tallahassee, Florida, LOUIS CAFFEESTA, Florida Center for Advanced Aero-Propulsion, Tallahassee, Florida — Cryogenic helium-4 has considerable potential in fluids research due to a very small kinematic viscosity, suitable to generate and study high Reynolds number turbulent flow within a compact laboratory apparatus. However, studying the flow in helium-4 has been challenging largely due to the lack of effective visualization and velocimetry techniques. Here we have assembled a novel instrumentation including a 335 cm long horizontal cryogenic helium channel with a square 4cm\(^2\) cross-section. This allows us to generate fully-developed turbulent pipe flows with Reynolds numbers above \( 10^6 \). We implement a unique molecular tagging velocimetry (MTV) method based on tracking two parallel thin He\(_2\) molecular tracer lines created perpendicular to the pipe wall with an adjustable distance via femtosecond laser-field ionization. By observing the displacement and distortion of the tracer lines, we can measure the near-wall mean velocity profile, velocity fluctuation profile, as well as both the transverse and longitudinal spatial velocity correlations. We also report the pressure drop data acquired from the experimental channel using a differential pressure transducer, then the friction factor coefficient can be determined.

4:01PM G11.00002 Experimental study for turbulent pipe flow at high Reynolds number using LDV - Turbulent intensity profile and influence of measurement volume, NORIYUKI PURIUCHI, National Institute of Advanced Industrial Science and Technology, EISUKE KUSANO, Nagoya Univ., YUKI WADA, Japan Atomic Energy Agency, YOSHIYUKI TSUJI, Nagoya Univ. — We have done new experiments for turbulent pipe flow at high Reynolds number, up to \( Re_{\tauRNA} = 300,000 \) using Hi-Reff. In the experiments, the friction factor was measured by the pressure drop along the pipe and the velocity was measured using LDV. As one of issues of the measurement, the spatial resolution of the measurement is very sensitive for the turbulent intensity for any measurement methods. With increasing Reynolds number, the relative measurement volume of LDV increases. This issue has been discussed for the hot-wire measurement, however still not done for the LDV. In this paper, the influence of the measurement volume of LDV at the wall bounded flow is studied as first. The measurement volume of LDV is controlled by the changing the insertion angle of the laser. Based on the relation between the normalized spatial resolution \( L^* \) and Reynolds number, the criteria for the measurement at high Reynolds number is clarified. Finally, the trend with Reynolds number of turbulent intensity profile for streamwise and wall-normal component are reported. Those data are compared with DNS data.

4:14PM G11.00003 Numerical investigation on very-large-scale motions and the amplitude modulation in the atmospheric boundary layer at very high Reynolds number, HEHE REN, SHIJUN LAIMA, HUI LI, Harbin Institute of Technology, KEY LAB OF SMART PREVENTION AND MITIGATION FOR CIVIL ENGINEERING DISASTERS TEAM — Wall Model Large Eddy Simulations (WMLES) were carried out to investigate the spatial features of very-large-scale motions (VLSMs) in the atmospheric boundary layer flow under different surface roughness at very high Reynolds number, \( Re > 10^6 \). The simulation results display good agreement with field observation and experimental data. By pre-multiplied spectral analysis, the VLSMs reduces or even disappears with increasing roughness, which supports the Bottom-up mechanism indirectly. From the perspective of spatial correlation of flow field, the structural characteristics of VLSMs under various roughness were shown well with observation data. Furthermore, the amplitude modulation (AM) that exerted by the outer layer large-scale motions on the near-wall small-scale motions was discussed. It was found the negative maximum correlation decreases with increasing Reynolds number. And there is an approximate collapse of correlation over different magnitude in Reynolds number when scaled with outer variables. Finally, the physical meaning of the reversal in sign of correlation corresponds to the cross-point of small-scale turbulent intensity and the local peak of energy distribution was found.

4:27PM G11.00004 Inertial-layer Mean Velocity Profiles for extreme Reynolds number flows, FABIO RAMOS, HAMIDREZA ANBARLOOEI, DANIEL CRUZ, Federal University of Rio de janeiro — For fully developed statistically stationary channel and pipe flows with smooth walls, any averaged quantity of the flow at a distance \( y \) from the wall can be specified by the control parameters \( \nu, \nu_y \), and \( y \). By the Pi theorem, there exist three non-dimensional groups that can be formed from the combination of \( u(y) \) or \( (u(y)) \), and those quantities. In an earlier work, by observing that center of the log-law scales as the geometric mean for \( \delta^{\nu} \), we have proposed an attached eddy framework, which results on a new friction factor formula for extreme Reynolds number, namely \( f \sim \frac{\nu}{Re_{\delta^{\nu}}^{1.75}} \). In this work, by assuming incomplete self-similarity, we show that the new friction factor is compatible with a new MVP formula, namely \( \Delta u(y) = \nu_y(B + (y) \sqrt{y}) \), which in wall units result in the new expression \( u^+ = A(y^{+1/2} + (y) \sqrt{y})^{1/6} \). This formula, with only two free parameters, results in a very good fit for the MVP data obtained from Princeton superpipe experiments, for a large range of extreme Reynolds number, \( Re > 10^6 \), and for a large radial extension above the log-law range.
4:40PM G11.00005 Invariant PDF profile in the log-region of high-Re-number turbulent boundary layer , YOSHIYUKI TSUJI, Nagoya University, ATSUSHI IDO, Railway Technical Research Institute Japan, MICHIKO NISHIOKA, Osaka Prefecture University — The probability density function (pdf) of a streamwise velocity component is studied in zero-pressure gradient boundary layers. From analyzing the data up to $Re_\theta \sim 80000$, it is found that pdfs have self-similar profiles in the log-law region of mean velocity. Pdf profiles asymptote to the universal shape very close to the Gaussian, but are positively skewed at the core region, indicating smaller values in the tail parts. In the log-law region of turbulence intensity, pdf is positively skewed slightly. These characteristics are summarized depending on the Reynolds number.

4:53PM G11.00006 The energy budget at the outer peak of $u'^2$ in turbulent pipe flow.¹, JONATHAN MORRISON, JOSE FERNANDEZ VICENTE, Imperial College — We use the NSTAP data from the Princeton superpipe (Vallikivi PhD thesis 2014) to examine the spatial & spectral energy fluxes close to the outer peak in $u'^2$ in the range of Reynolds numbers, 2.1 $\times$ 10^6 $\leq Re_D \leq 6.0 \times 10^6$, for which the ratio of hot-wire length to Kolmogorov length scale is $l/\eta \approx 10$. Previous results (Hultmark et al. PRL, 108, 2012) suggest that the outer peak emerges at $Re_D \approx 1.1 \times 10^6$, its position exhibiting a locus $y_m^+ = 0.23(Re^{-0.67})$. We note that this is close to the position of the well-known “mesolayer”, which we have also described as the intermediate layer with scaling ($y_m^+ \propto \sqrt{Re} \tau \eta$, where $\eta$ is the rms velocity at $y = \eta$ (Dianw & Morrison, TSFP11 – see also the presentation in the session, “Turbulent Boundary Layers”). It is straightforward to show that the locus of $u_m$ is close to that for the production, $F_m(u'^2)$, where the local-equilibrium approximation approximately holds. Therefore, spectral dynamics are most Kolmogorov-like because spatial transport is minimal. We examine the inertial scaling of the axial velocity spectra and low-order structure functions to explain the importance of intermediate scaling.

5:06PM G11.00007 Thermal transport in hypersonic turbulent boundary layers at high-Reynolds numbers¹, JEAN SANTIAGO, HPCVLab U. of Puerto Rico-Mayaguez, NATHAN TICHENOR, Texas A&M University, GUILLEMROR ARAYA, HPCVLab U. of Puerto Rico-Mayaguez — The evolution of thermal spatially-developing turbulent boundary layers (SDTBL) is studied experimentally and numerically at the hypersonic regime. Experiments were performed in a high-speed blow-down wind tunnel facility located in the National Aerothermochemistry and Hypersonics Laboratory (NAL) at Texas A&M University (TAMU) over a zero-pressure gradient (ZPG) adiabatic flat plate at a Mach number of 4.9 and a Reynolds number of 9,000 based on freestream density, momentum thickness, freestream velocity and wall viscosity. Direct Numerical Simulation (DNS) and Large Eddy Simulation (LES) of SDTBL at low and high Reynolds numbers are designed in harmony with experiments. Turbulent inflow information is generated via the dynamic rescaling-recycling approach (J. Fluid Mech., 670, pp. 581-605, 2011), which is extended to compressible flows. DNS and LES results of the field velocity are validated by particle image velocimetry (PIV) experiments. Focus is given to the assessment of Reynolds number on the thermal fluctuations and turbulent heat fluxes, as well as their vertical transport. This presentation will emphasize the calibration effort of the numerical model in order to capture the measured flow structure.

5:19PM G11.00008 Inter-scale modulation in pipe flows at high $Re_c$¹, XIABO ZHENG, YE LI, NAOCE, Shanghai Jiao Tong University, GABRIELE BELLANI, LUCIA MASCOTELLI, ALESSANDRO TALAMELLI, Dipartimento di Ingegneria Industriale, Università di Bologna — Hot-wire measurements of streamwise velocity are conducted in the large-scale pipe-flow facility CicloPe in the friction Reynolds number range $7800 < Re_c < 40 000$. Measurements have been performed both with a rake of 5 synchronized probes arranged at different radial locations, and through radial scans with a single wire traversing the whole pipe radius. Correlation analysis is used to extract geometric features of coherent structures and inter-scale modulation in turbulent pipe flows. The $Re_c$-independence of geometric features is shown. Very-large-scale motions keep inclining and vertical coherence to the wall in the whole pipe radius, while large-scale motions with local coherence gradually become isotropy as reference moves far away from the wall. One-point and two-point amplitude modulation (AM) show that phase difference between large- and small-scales is linear to logarithm of $y/R$ for AM, but is independent on wall-normal location for opposite modulation. In log layer, time-delay for zero-modulation present linear-log relation to $y/R$, but in whole pipe radius, zero-modulation keeps inclining with 4 degree in $\rho^1/\deltam$ map.

¹EPSRC Grant no. EP/I037938

5:19PM G11.00008 Inter-scale modulation in pipe flows at high $Re_c$¹, XIABO ZHENG, YE LI, NAOCE, Shanghai Jiao Tong University, GABRIELE BELLANI, LUCIA MASCOTELLI, ALESSANDRO TALAMELLI, Dipartimento di Ingegneria Industriale, Università di Bologna — Hot-wire measurements of streamwise velocity are conducted in the large-scale pipe-flow facility CicloPe in the friction Reynolds number range $7800 < Re_c < 40 000$. 3:48PM G12.00001 Honoring Ted OBrien: High order methods for filtered and probability density function models , GUSTAAF JACOBS, San Diego State University — The systems of partial differential equations that govern probability and filtered density function models can be solved directly using numerical methods. Oftentimes, this type of system is also solved using a combination of Monte-Carlo and stochastic differential equations. If the density function model is coupled with another model that has feedback, as can occur in multi-physics or multi-phase environments, then the numerical coupling must be consistent for both approaches to obtain an accurate numerical solution. In this talk, I will discuss recent progress in the development of high order accuracy methods for models governing, chemically reaction and/or particle-laden, high-speed flows with shocks. High order distribution functions and weighted interpolations combined with spectral elements methods are presented and are shown to give accurate results for time-dependent problems that require long time integration.
the turbulent strain-rate and the destruction of iso-surface area due to the combined effects of diffusion and surface curvature. The T/NT interface in a turbulent free shear flow, and a passive scalar field which represents an inert tracer such as dye concentration or the vorticity magnitude, which represents in its transport equation. Iso-surface properties, such as the surface area, are evaluated by converting the surface integrals to volume integrals.

FOLUSO LADEINDE, Stony Brook University — The authors initial studies on compressible turbulence and combustion reported.

variants so that stochastic methods are required for its solution; in the present work the stochastic fields method is utilised. It has been applied to simulate the evolution of self-excited thermo-acoustic instabilities in a gas turbine model combustor, using a fully compressible formulation. An unstable operating condition in the PRECCINSTA combustor, involving flame oscillation driven by thermo-acoustic instabilities, is the chosen target configuration. The flame’s self-excited oscillatory behaviour is successfully captured without any external forcing being involved. Power spectral density analysis of the oscillation reveals a dominant thermo-acoustic mode at a frequency of 30 Hz providing remarkably good agreement with experimental observations. Moreover, the predicted limit-cycle amplitude closely matches the experimental value obtained with rigid metal combustor side walls.

4:14PM G12.00003 Physics-Based vs. Data-Driven Modeling for Turbulence and Combustion, SHARATH GIRIMAJI1,2, Ocean and Aerospace Engineering, Texas AM University — Honoring Ted O’Brien: Ted O’Brien had a long and distinguished career in modeling and computing chemically reacting turbulent flows. He made important contributions toward modeling/computation of auto-ignition in turbulent mixtures, conditional scalar dissipation, PDF (probability density function) methods and mapping closure methods. Currently, drive toward use of data-driven models is pervasive in nearly all fields involving complex phenomena including turbulent combustion. This presentation will discuss some of the benefits and challenges of using data-driven models for prediction of reacting turbulent flows. For a variety of turbulence and combustion features, we will compare the strengths and weaknesses of data-driven modeling against that of physical modeling. Specifically will we examine the general capabilities of data-driven approaches for handling (i) distant interactions – specifically non-local effects due to the elliptic nature of pressure and (ii) purely local process of chemical reactions. The talk will conclude with some recommendations on synergistically combining physics-based and data-driven approaches for developing predictive tools for turbulence and combustion.

1This paper is being submitted to: Session 31.5 (Honoring Ted O’Brien)

4:27PM G12.00004 Differential diffusion modelling in transported PDF simulations of turbulent flames1, ZHUYIN REN, Tsinghua University, HUA ZHOU, University of New South Wales, TIANWEI YANG, Tsinghua University — Honoring Ted O’Brien. The modelling strategy to incorporate differential diffusion effects in transported density function method (PDF), particularly in the context of large eddy simulation (LES) is proposed. Differential diffusion at the filter scale is resolved by the mean drift term in composition equations, while subgrid differential diffusion is modelled by the augmented mixing models that can account for differential mixing rates for each individual species. Both RANS/PDF and LES/FDF simulations of a jet-in-hot-coflow methane-hydrogen flame have been performed to investigate the effects of differential diffusion on flame characteristics.

4:40PM G12.00005 Mathematical Models For Eulerian Conditional Statistics in a Complex Turbulent Flow, JAMES HILL, Iowa State University (Retired), EMMANUEL HITIMANA, MICHAEL OLSEN, RODNEY FOX, Iowa State University — Honoring Ted O’Brien. Conditional moment closure (CMC) methods were developed for predicting turbulent reacting flows. However, conditional averages appear as unclosed terms that need to be modeled. In the present work the linear approximation and PDF gradient models were used to predict the conditional mean velocity and mixture fraction and compare with experimental data obtained for a macroscale multi-inlet vortex chemical reactor (macro-MIVR) using laser diagnostic techniques. The results for velocity conditioned on mixture fraction show that the linear model works well in a low turbulence region away from the reactor center. The PDF model with an isotropic turbulent diffusivity performs poorly for the tangential and axial conditional velocities, but a modified version that considers three components of turbulent diffusivity is better. Furthermore, the mixture fraction conditioned on the velocity vector components has a more linear behavior near the reactor center, where the probability density function (PDF) of the mixture fraction is close to a Gaussian distribution.

4:53PM G12.00006 On the kinematics of scalar iso-surfaces in a turbulent, temporally developing jet, BRANDON BLAKELEY, WEIRONG WANG, DUANE STORTI, JAMES RILEY, University of Washington — The kinematics and dynamics of scalar iso-surfaces in turbulent flows is of fundamental importance for a number of problems, e.g., the stoichiometric flame surface in non-premixed combustion or the turbulent/non-turbulent interface in turbulent shear flows. We investigate the effects of turbulence on iso-surfaces by examining the surface area density, Σ, and its evolution. Using direct numerical simulation of a temporally developing jet and a novel algorithm for evaluating iso-surface properties, we report on the direct computation of Σ and the terms in its transport equation. Iso-surface properties, such as the surface area, are evaluated by converting the surface integrals to volume integrals on a regularly-sampled grid. In particular, we analyze the behavior of two different scalar iso-surfaces: the vorticity magnitude, which represents the T/NT interface in a turbulent free shear flow, and a passive scalar field which represents an inert tracer such as dye concentration or the mixture fraction. Differences between the evolution of the two iso-surfaces will be addressed, such as the production of iso-surface area due to the turbulent strain-rate and the destruction of iso-surface area due to the combined effects of diffusion and surface curvature.

5:06PM G12.00007 Investigation of Two-Phase Supersonic Combustion in Hypersonic Flight, FOLUSO LADEINDE, Stony Brook University — The authors initial studies on compressible turbulence and combustion in high-speed flows were done via DNS in collaboration with the Late Professor Edward E. O’Brien in several joint publications on the topic. However, the authors focus has evolved, and the transport of momentum, energy, and chemical species in supersonic spray combustion for systems that approximate the scramjet engine in hypersonic flight is of current interest. Many advantages can be derived from the use of liquid fuels, such as the higher heat release and ease of storage and handling. The system in question is complicated by the interaction of many effects, including those due to combustion, evaporation, turbulence, shock waves, and their interactions. Consequently, many studies have addressed these issues. Based on the parameters for the application of interest, the point-particle approach via the Eulerian-Lagrangian formulation is followed in the present endeavor. This approach introduces explicit force and energy sources, some of which involve history integrals. The significance of these sources is investigated in terms of their roles in the rather complex drop breakup mechanism in the presence of shockwaves, and the eventual evaporation and combustion to provide the needed propulsive force. The progress made by the author will be reported.
The resulting modifications of vertical heat transport and solute concentration are investigated at varying shear rates. fingering instability, leading to highly anisotropic DDC dynamics associated with the formation of regular sheets of the slowly-diffusing scalar. U. of North Carolina pipes 1 groups, such as the Rossby number, the Froude number, and the Bingham number. a critical transition, leads to a complete removal of the displaced fluid. The results are quantitatively analyzed using the flow dimensionless experimental parameters, such as the pipe inclination angle, the density difference, and most importantly the pipe rotation speed. For both speed imaging techniques. The analysis of our experimental results reveals that the displacement process can be affected by variations of the yield stress fluid. The experiments are performed in a long transparent pipe so that the displacement flow patterns can be visualized using high speed imaging techniques. The experimental results can be affected by variations of the experimental parameters, such as the pipe inclination angle, the density difference, and most importantly the pipe rotation speed. For both Newtonian and yield stress displacements, increasing the pipe rotation speed enhances the transverse mixing between the fluids and, above a critical transition, leads to a complete removal of the displaced fluid. The results are quantitatively analyzed using the flow dimensionless groups, such as the Rossby number, the Froude number, and the Bingham number.

3:48PM G13.00001 Buoyant displacement flows of miscible fluids in axially rotating pipes 1. SEYED MOHAMMAD TAGHAVI, SHAN LYU, Universit Laval — This work experimentally considers the effects of a pipe axial rotating motion on buoyant displacement flows of miscible fluids in an inclined pipe. A heavy Newtonian fluid displaces a light Newtonian or yield stress fluid. The experiments are performed in a long transparent pipe so that the displacement flow patterns can be visualized using high speed imaging techniques. The experimental results can be affected by variations of the experimental parameters, such as the pipe inclination angle, the density difference, and most importantly the pipe rotation speed. For both Newtonian and yield stress displacements, increasing the pipe rotation speed enhances the transverse mixing between the fluids and, above a critical transition, leads to a complete removal of the displaced fluid. The results are quantitatively analyzed using the flow dimensionless groups, such as the Rossby number, the Froude number, and the Bingham number.

4:01PM G13.00002 Nonnormal transient growth of triadic resonant internal gravity waves, KEVIN HA, JEAN MARC CHOMAZ, Ecole Polytechnique, SABINE ORTIZ, ENSTA — Triadic resonant instability is a key component in the understanding of the dissipation process of inertia gravity waves for geophysical applications like oceanic circulation, which is still incompletely understood. A key process in the oceanic circulation is the vertical mixing, which makes it possible for dense deep water to reach the surface. Global warming regulation by the ocean then depends on mechanisms controlling the vertical mixing of deepwater masses. It was recently predicted by Garrett & Kunze (2007) that triadic resonances are responsible for inertial gravity waves generated by interaction between the barotropic tide and global topography (continental shelf, underwater mount). The present work focuses on the energy approach of the triadic resonant instability and demonstrates that due to the nonnormality of the evolution operator, stable triadic resonant interactions result in a transient amplification of perturbation energy. Computations show that they can lead to a longer and more intense transient growth than unstable triads. Instead of being related to the differential growth of a stable and an unstable modes like for unstable triads, the transient growth of stable triads originates from the differential rotation (i.e. phase shift) of two stable eigenmodes.

4:14PM G13.00003 Mechanisms of drag enhancement on bodies settling in a linearly stratified fluid, JACQUES MAGNAUDET, Institut de Mecanique des Fluides de Toulouse, CNRS and Universite de Toulouse, France, JIE ZHANG, State Key Laboratory for Strength and Vibration of Mechanical Structures, School of Aerospace, Xian Jiaotong University, China, MATHIEU MERCIER, Institut de Mecanique des Fluides de Toulouse, CNRS and Universite de Toulouse, France — Using DNS, we compute the flow past a sphere settling with constant speed in a linearly stratified fluid over a wide range of Reynolds, Prandtl and Froude numbers. Thanks to a rigorous mathematical decomposition procedure, we identify the various contributions to the stratification-induced drag, especially that due to the dragging of light fluid around the body and within its wake, and that induced by the distortion of the vortex lines. Combining DNS results and scaling laws provided by the dominant balances in the density and momentum equations, we show how these two contributions vary with the control parameters. It turns out that for large Prandtl numbers and Reynolds numbers up to $O(10^4)$, the drag enhancement is essentially due to the specific structure of the vorticity field set in by buoyancy effects, while effect of the dragging of light fluid near the body surface takes over for larger Reynolds numbers.

4:27PM G13.00004 Decay of convective boundary layer and effect of decreasing rate of surface heat flux, MINGXIANG ZHAO, LIAN SHEN, University of Minnesota — Decay of convective boundary layer (CBL) is a model of the late-afternoon transition of the unstably stratified atmospheric boundary layer. In this study, simulations were performed to investigate the decay process under different decreasing rates of the surface heat flux. We decomposed the turbulence fluctuations into different scales to investigate their responses to the decreasing surface heat flux. It is shown that the decreasing rate of the large-scale vertical velocity fluctuations is much greater than that of the small-scale fluctuations regardless how fast the decreasing rate of the surface heat flux is. Moreover, the large-scale fluctuations experience several stages of temporary enhancements due to the local upward heat flux, while the small-scale fluctuations decreases monotonously. For the decay process of temperature fluctuations, the present study showed essential differences from that of small-scale fluctuations. For instance, the temperature fluctuations respond to the decreasing surface heat flux more quickly and the small-scale fluctuations decay faster than the large-scale fluctuations.

4:40PM G13.00005 Influence of shear on fingering dynamics in double diffusive convection, PEJMAN HADI SICHANI, CRISTIAN MARCHIOLI, University of Udine, FRANCESCO ZONTA, ALFREDO SOLDATI, TU Wien — We examine the effect of shear on double-diffusive convection (DDC) in a confined fluid layer under the Oberbeck-Boussinesq condition. DDC is characterized by the competing action of a stably-stratified, rapidly-diffusing scalar temperature and an unstably-stratified, slowly-diffusing scalar solute concentration. This problem has five governing parameters: The thermal Prandtl number, $Pr_T$ (momentum to thermal diffusivity ratio); the thermal Rayleigh number, $Ra_T$ (measure of the fluid instability due to temperature and density differences); the Lewis number, $Le$ (thermal to solute diffusivity ratio); the density stability ratio, $R_i$ (measure of the effective flow stratification), and the shear rate, $\Gamma$. We investigate double-diffusive fingering subject to uniform shear in a wall-bounded domain by performing a campaign of highly-resolved numerical simulations in the $(Pr_T, Ra_T, Le, R_i, \Gamma)$ parameter space. Preliminary results show that shear tends to dampen the growth of fingering instability, leading to highly anisotropic DDC dynamics associated with the formation of regular sheets of the slowly-diffusing scalar. The resulting modifications of vertical heat transport and solute concentration are investigated at varying shear rates.
4:53PM G13.00006 Estimation of mixing in a lock-exchange flow using molecular tagging velocimetry and thermometry, TANMAY AGRAWAL, JIMMY PHILIP, JOE KLEWICKI, The University of Melbourne — Gravity currents produced by a lock-exchange experiment are studied using the single-component version of molecular tagging velocimetry (MTV) in conjunction with its thermal counterpart, molecular tagging thermometry (MTT). The experiments are conducted in a Perspex tank of 2.0 m x 0.2 m x 0.2 m where the lock is located mid-way. Therefore, the current is studied only during the slumping phase and there are no transitions associated with the end-wall reflection. For these experiments, the initial density difference is created by introducing a thermal inhomogeneity on either side of the lock as compared to the general experimental practice of dissolving a salt on one side. The flow is first visualized by mixing a dye on the heavier side to fully distinguish the experimental parameters. Subsequently, MTV, MTT images are acquired that contain approximately 1000 data points distributed across the interface of hot and cold fluid. This high-resolution velocity and temperature data is then used to quantify the mixing being taken place at the interface. Specifically, background potential energy of the flow is evaluated over time to estimate the extent of irreversible mixing while an equivalent Thorpe scale is calculated to estimate the size of overturning eddies.

5:06PM G13.00007 Wall-bounded stably-stratified turbulence at high Reynolds number, FRANCESCO ZONTA, Institute of Fluid Mechanics and Heat Transfer, TU Wien, PEJMAN HADI SICHANI, Polytechnic Department, University of Udine, ALFREDO SOLDATI, Institute of Fluid Mechanics and Heat Transfer, TU Wien — Wall-bounded stably stratified turbulence is encountered in many industrial and natural processes. Examples include fluid motion in heat transfer devices or transport/mixing of organic species in terrestrial water bodies. In this work, we focus on stably stratified turbulent channel flow at high shear Reynolds number Reτ. We perform a campaign of pseudo-spectral direct numerical simulations (DNS) of the governing equations, written under the Boussinesq approximation, in the shear Richardson number space Riτ = Gr/Reτ^2 (which measures the relative importance of buoyancy compared to inertia, with Gr the Grashof number). In particular, we fix the Reynolds number Reτ = 1000 and we change Gr so to cover a broad range of Riτ values. For increasing Riτ, turbulence is sustained only near the boundaries, whereas non-turbulent wavy structures (Internal Gravity Waves, IGW), also favored by the presence of intermittent bursts, are observed at the core of the channel. Naturally, the presence of IGW alters the overall transfer rates of momentum and heat, as well as the mixing efficiency of the flow. We believe that the present results may give important contributions to future turbulence parametrization and modeling in this field.

5:19PM G13.00008 Intermittency and modal dynamics of stratified mixing at oceanographic scales, ALBERTO SCOTTI, University of North Carolina at Chapel Hill, PIERRE-YVES PASSAGGIA, Prisme Lab. University of Orleans — Stratified turbulent channel flows are known to generate strongly intermittent dynamics where the flow alternates irregularly between the growth of stratified shear instabilities, regions of decaying turbulence, and quasi laminar states. Quantifying intermittency at oceanic scales from field measurements or numerical simulations may become intractable because of sampling issues. The former may offer too few spatial measurements while the latter may prove too computationally expensive. Laboratory experiments provide an interesting alternative and allow for circumventing both difficulties. This talk therefore explores this issue with the aid of an experimental dataset acquired in the UNC Joint Fluid Lab. In a large tank, we generate shear-driven turbulent mixing that spans a significant range of the parameter space encountered in the ocean and for several thousands of eddy turnover times. Hot wire and conductivity measurements are paired with PIV and LIF measurements in a plane to extract the modal features of the flow and their intermittency. These measurements are finally compared with measurements of the bulk Richardson number which is found to be key driver of these dynamics. We finally discuss the implication for the interpretation of field data.

3:48PM G14.00001 Do steady rolls maximize heat transport in truncated models of Rayleigh-Bénard convection?1, DAVID GOLUSKIN, University of Victoria, CHARLES R. DOERING, University of Michigan, ANUJ KUMAR, University of California, Santa Cruz, MATTHEW OLSON, University of Michigan — In Rayleigh-Bénard convection, steady rolls are the simplest nonlinear states. They exist for all Rayleigh numbers (Ra) above the primary instability but are unstable at large Ra. Heat transport by steady rolls is comparable to that by turbulent convection if the aspect ratio of rolls is varied with Ra to maximize heat transport (Waleffe et al., Phys. Fluids 27, 2015). Here we ask: do steady rolls transport more heat than any other flows, including turbulent or unstable time-periodic flows? Answering this question in the affirmative requires computing exact upper bounds on heat transport, and showing that steady rolls saturate the bounds. Exact bounds for the governing PDEs are beyond current capabilities, so we instead study ODE models of increasing dimension, each derived as a Galerkin truncation of the PDEs governing 2D convection between free-slip plates. For the ODEs we compute sharp upper bounds on heat transport by using polynomial optimization. In particular, upper bounds are provided by solutions to convex optimization problems, whose constraints require certain expressions to be sums of squares of polynomials, and which are solved numerically using semidefinite programming. To find the states that saturate these bounds, we perform numerical bifurcation analysis.

4:01PM G14.00002 Numerical study of thermal transfer in Rayleigh-Bénard convection under rarefied gas conditions, GIANLUCA DI STASO, BIJAN GOSHAYESHI, FEDERICO TOSCHI, HERMAN CLERCX, Eindhoven University of Technology — The Rayleigh-Bénard problem has been analyzed in depth theoretically, experimentally and numerically under a broad range of conditions such as small and large Prandtl number, high Rayleigh number turbulent convection, non-altregnate compressibility effects, as well as under rotation. The large majority of these studies have in common the underlying assumption of a continuum flow, i.e. the molecular mean free path is much smaller than any characteristic macroscopic spatial scale of the flow. In this contribution, we depart from this assumption and we numerically study the final state of a 2D Rayleigh-Bénard system under rarefied gas conditions using the Direct Simulation Monte Carlo method (DSMC), the standard particle-based numerical method for simulating rarefied gas flows. By collecting a large number of statistical samples, we quantitatively measure the heat flux enhancement when convection is present and we determine the influence of rarefaction conditions on the maximum attainable heat flux. Finally, we show that onset of convection is found only for a limited range of Rayleigh number and this range is reduced as the degree of rarefaction increases.
4:14PM G14.00003 Transition of the flow dynamics in two-dimensional Rayleigh-Bénard convection1. ZHENYUAN GAO, Department of Mechanics and Aerospace Engineering, Southern University of Science and Technology, YUN BAO, Department of Mechanics, Sun Yet-sen University, SHIDU HUANG, Department of Mechanics and Aerospace Engineering, Southern University of Science and Technology — We investigate the flow dynamics in two-dimensional Rayleigh-Bénard convection through high resolution direct numerical simulation, with the Rayleigh number Ra range being $10^7$ to $10^9$ and the Prandtl number Pr fixed at 4.3. It is found that there exists a transitional Rayleigh number $Ra_c$ at which the flow pattern changes significantly and the large-scale circulation (LSC) evolves from an elliptical shape into a circular one. Detailed Fourier mode analysis reveals that, while the single-roll mode becomes weaker and other modes become stronger during the transition, all the flow modes experience violent fluctuations. This is also manifested by the sharp change of the local turbulent fluctuations near $Ra_c$, in both magnitude and Ra-dependent scaling. We understand this transition by stability analysis.

4:27PM G14.00004 Using Persistent Homology to Compare Chaotic Dynamics Between Experiments on and Simulations of Rayleigh-Bénard Convection1. BRETT TREGONING, Georgia Institute of Technology, SAIKAT Mukherjee, Virginia Polytechnic Institute and State University, RACHEL LEVANGER, University of Pennsylvania, MU XU, Columbia University, JACEK CYRANKA, University of California San Diego, KONSTANTIN MISCHAIKOW, Rutgers University, MARK PAUL, Virginia Polytechnic Institute and State University, MICHAEL SCHATZ, Georgia Institute of Technology — Persistent homology is a tool from algebraic topology that can be used to efficiently detect pattern features in image data. In the spatio-temporally chaotic flow known as spiral defect chaos in Rayleigh-Bénard convection, we explore the use of pattern features detected by persistent homology as a proxy for fundamental dynamical quantities that are not observable in experimental data but can be calculated from simulations, such as leading-order Lyapunov vectors. In simulations, we have identified that convective plumes are highly correlated with the leading-order Lyapunov vectors; however, we find that plumes appear in experiments at distinctly different rates than for Boussinesq simulations at the same parameter values. We describe work to resolve this discrepancy by accounting for non-Boussinesq effects in both experiments and simulations.

1This work is supported under NSF grant DMS 1622113, DMS 1125302, CMMI-1234436, and DARPA HR0011-16-2-0033.

4:40PM G14.00005 Marginally stable Rayleigh–Bénard convection. BAOLE WEN, University of Michigan, ZIJING DING, University of Cambridge, GREGORY CHINI, University of New Hampshire, RICH KERSWELL, University of Cambridge, UNIVERSITY OF MICHIGAN COLLABORATION, UNIVERSITY OF NEW HAMPSHIRE COLLABORATION, UNIVERSITY OF CAMBRIDGE COLLABORATION — We propose a new strategy to predict the heat transport in 2D Rayleigh–Bénard convection between stress-free isothermal boundaries. The Constantin–Doering–Hopf (CDH) variational framework, in which the temperature is decomposed into a background profile plus a fluctuation field and the background profile is required to satisfy a marginal energy-stability constraint, provides a formalism for determining boundaries. In the spatio-temporally chaotic flow known as spiral defect chaos in Rayleigh–Bénard convection, we explore the use of pattern features detected by persistent homology as a proxy for fundamental dynamical quantities that are not observable in experimental data but can be calculated from simulations, such as leading-order Lyapunov vectors. In simulations, we have identified that convective plumes are highly correlated with the leading-order Lyapunov vectors; however, we find that plumes appear in experiments at distinctly different rates than for Boussinesq simulations at the same parameter values. We describe work to resolve this discrepancy by accounting for non-Boussinesq effects in both experiments and simulations.

4:53PM G14.00006 Effect of aspect ratio on the Rayleigh convection of Maxwell viscoelastic fluids in a cavity heated from below1. ILDEBRANDO PEREZ-REYES, Universidad Autonoma de Chihuahua, ALEJANDRO SEBASTIAN ORTIZ-PEREZ, Universidad Autonoma de Baja California, NESTOR GUTIERREZ-MENDEZ, Universidad Autonoma de Chihuahua, FLUIDS, HEAT AND MASS TEAM — Interest results, of the effect the parity of convective rolls, on the Rayleigh convection in a Maxwell viscoelastic fluid confined in a 2D cavity are presented. A linear stability analysis have shown how the fluid stability changes for different values of the aspect ratio ranging from 0.1 to 10. It was found that vertical and horizontal parity of the temperature and velocity solutions, related to parity of the number of rolls distributed horizontally or vertically, gives different stability scenarios. On the other hand, kinks also appear in the curves of criticality, which is also found in the stability of newtonian fluids which also depend on the symmetry of the solutions. Results and physical mechanisms shall be presented in terms of plots of the critical Rayleigh number and the frequency of oscillation for different cases encompassing perfect thermal conducting, or insulating, lateral, or horizontal, walls. Different values of the dimensionless relaxation time $F$ are considered to discuss the physical mechanism of instability for fixed values of the Prandtl number $Pr$ as well.

5:06PM G14.00007 Thermal convection over a fractal surface1. SRIRKANT TOPPALADOODDI, ANDREW WELLS, University of Oxford, CHARLES DOERING, University of Michigan, JOHN WETTLAUFER, Yale University & Nordita — We use well resolved numerical simulations to study Rayleigh–Bénard convection in cells with a fractal boundary in two dimensions for $Pr = 1$ and $Ra \in [10^7, 2.15 \times 10^9]$. The fractal boundaries are functions characterized by power spectral densities $S(k)$ that decay with wavenumber as $S(k) \sim k^{-p}$ ($p < 0$). The degree of roughness is quantified by the exponent $p$ with $p < -3$ for smooth (differentiable) surfaces and $-3 \leq p < -1$ for rough surfaces with Hausdorff dimension $D_H = \frac{1}{2} (p + 5)$. By computing the exponent $\beta$ in power law fits $Nu \sim Ra^\beta$, where $Nu$ and $Ra$ are the Nusselt and the Rayleigh numbers, we observe that heat transport increases with roughness. For $p = -3.0$, $-2.0$ and $-1.5$ we find, respectively, $\beta = 0.256$, $0.281$ and $0.306$. For a given value of $p$ we observe that the mean heat flux is insensitive to the details of the roughness.

and nominally 2D flow structures, while varying jet size, speed, height and angle, and fluid properties such as surface tension and viscosity.

3:48PM G15.00001 How is the eigenframe of the rate-of-strain tensor perturbed by density gradients? . DOMINIQUE FRATANTONIO, CHRIS LAI, JOHN CHARONKO, KATHY PRESTRIDGE, Los Alamos National Laboratory — We present an experimental study on a variable-density turbulent jet. The jet’s three-dimensional density and velocity fields have been reconstructed using a time-resolved simultaneous stereoscopic PIV and planar LIF system together with the Taylor’s frozen turbulence hypothesis. The obtained dataset is then analyzed to understand how density gradients perturb the eigenframe of the rate-of-strain tensor whose alignments with the vorticity vector govern the key turbulence process of vortex-stretching.

4:01PM G15.00002 Air entrainment by 2D plunging jets1 . NICOLE FARIAS, SIMO A. MKIHARJU , UC Berkeley — Air entrainment from liquid plunging jets are commonly found in nature and industry applications. As a result, this phenomenon has been the focus of many studies in the past, which showed it to have a significant contribution to the energy and mass transfer between gas and liquids. Air entrainment was also discovered to be a function of various parameters, such as jet impact velocity, geometry, fluid properties, and resulting jet instabilities. Due to the complex multiphase flow involved, no exhaustive characterization or theory is yet available, and limited data has been published on the dynamics within the entrainment zone once entrainment becomes significant enough to make the flow optically opaque. We study 2D plunging jets using high-speed video, point probes and O(10kHz) 2D X-ray densitometry to examine the air entrainment and nominally 2D flow structures, while varying jet size, speed, height and angle, and fluid properties such as surface tension and viscosity. We span Reynolds numbers from 7 to 25 x10^3, and Weber numbers from 0.3 to 40.4. The high-speed X-ray densitometry we employ enables time-resolved analysis of phase fraction in large areas with greater efficiency and detail than feasible utilizing point probes alone.

4:14PM G15.00003 The combined effect of internal and external intermittency in turbulent jet flows1 . MICHAEL GAUDING, YACINE BRAHAMI, LUMINITA DANAILA, EMILEN VAREA, CORIA — The combined effect of internal and external intermittency on the statistical properties of small-scale turbulence is investigated in a temporally evolving, planar turbulent jet flow. In turbulent jet flows, the phenomenon of external intermittency originates from a very thin layer, known as turbulent/non-turbulent interface, that separates the inner turbulent core from the outer irrotational surrounding fluid. The impact of external intermittency on small-scale turbulence is studied across the jet by the self-similarity solution of higher-order structure functions. It is shown that the scaling of structure functions exhibits a growing departure from the prediction of classical scaling solutions toward the edge. Empirical evidence is provided that this departure is primarily due to external intermittency and the associated break-down of self-similarity. By conditioning structure functions on an external intermittency parameter, it is shown that the self-similarity solution of structure functions can be recovered. The analysis is based on highly resolved direct numerical simulations.

4:27PM G15.00004 Structure of two-dimensional turbulent wall jets1 . SHIVSAI DIXIT, HARISH CHOUDHARY, ABHISHEK GUPTA, THARA PRABHAKARAN, Indian Institute of Tropical Meteorology (IITM), Pune, Maharashtra, India, ABHAY KUMAR SINGH, Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India — Two-dimensional turbulent wall jets find important applications in engineering and meteorology, and present unique features such as the non-monotone mean velocity profile, a region of counter-gradient momentum diffusion etc. that are very different from other canonical turbulent wall-bounded flows. We propose that the wall-jet flow structure consists of universal full free-jet outer flow and wall-scaled inner flow. We further argue that there exists strong, nonlinear inner-outer interaction which could lead to the Reynolds number dependence of the overlap layer in wall jets. We present experimental hotwire and PIV data from our wall jet setup, over a range of Reynolds numbers, to substantiate this view. Further, an overlap analysis of the mean velocity profile shows that the Reynolds-number-dependence of the overlap layer can be effectively absorbed into an intermediate coordinate leading to universal overlap description in terms of the intermediate variable. Spectra and correlation maps also show promising support for the proposed structure of wall jets.

4:40PM G15.00005 Optical measurement of the interaction between outwardly oriented, steady gas jets. FRANK AUSTIN MIER, SIMONE HILL, MICHAEL HARGATHER, New Mexico Tech — Nearby gas jets issuing into a quiescent environment interact with each other in various manners dependent on their relative spacing and orientation. While the study of a single turbulent jet is classical to fluid dynamics, and entrainment between parallel jets at varying spacing has been quantified, this investigation aims to determine how an outward projection will affect the jet interaction. Here, Particle Image Velocimetry (PIV) and high-speed schlieren imaging are performed to characterize this interaction. An experiment was designed to produce steady gas venting through custom orifice plates at a range of choked and un-choked stagnation pressures. Orifice plates produced jets offset at incremented angles from 0° to 60°. Downstream jet interactions and flow features were measured through high-speed schlieren images. The velocity profile findings are compared to the well-defined parallel jet case. This work provides a fundamental understanding of the flow structure and velocity field of outwardly directed jets with broad potential application, including the external fluid-dynamics of lithium ion battery venting failures.

4:53PM G15.00006 Bifurcating jet in transverse acoustic field. EIRIK ASOY, PhD, JOSE G. AGUILAR, Post-doctoral, NICHOLAS A. WORTH, JAMES R. DAWSON, Professor — The far-field of an axisymmetric round jet is usually characterized by the momentum flux at the nozzle exit. However, it has been shown that when the jet is submitted to external forcing, the far-field exhibits different behavior from a classical jet. We present experiments of an axisymmetric jet subjected to external forcing by placing the nozzle exit in a standing acoustic field by forcing a rectangular box with loud-speakers. Several forcing conditions at the nozzle exit, i.e., differences of transverse and longitudinal velocity oscillations, are actuated by placing the nozzle at different positions relative to the pressure node. Time-resolved Particle Image Velocimetry (PIV) combined with microphone measurements are used to characterize the flow field in a plane of interest and the acoustic fields. It is found that the jet bifurcates, i.e., splits into two or three separate momentum streams, at sufficiently high forcing levels when placed anywhere else than at a pressure anti-node. Furthermore, the flow field is asymmetric at any position between the pressure and velocity nodes. This asymmetry is symmetric across the pressure anti-node which is shown to be linked to the relative phase between transverse and longitudinal velocity oscillations.

5:06PM G15.00007 Reevaluating the jet breakup regime diagram. BEN TRETTEL, University of Texas at Austin — Identifying the regime of a liquid jet is necessary to determine the physical mechanisms causing breakup and consequently how to model the jet. Existing regime diagrams are based on a small amount of data classified by superficial visual characteristics, making these diagrams too inaccurate to reliably determine the correct regime. A more accurate regime diagram is developed using a large compilation of breakup length data combined with theory where the data is sparse. Improvements in the regime diagram include a new regime, the addition of the nozzle critical Reynolds number and the turbulence intensity as variables, and the recognition that how the regimes change with increasing velocity (i.e., Rayleigh to first wind-induced to second wind-induced to atomization) is not universal.

5:19PM G15.00008 Droplet size distribution along the near-field interface of immiscible turbulent jets. ERIC IBARRA, FRANKLIN SHAFFER, OMER SAVAS, UC Berkeley — This work examines the droplet distributions of submerged, immiscible, turbulent jets in the near field. Experiments consist of silicone oil jets of two viscosities submerged in a water tank. The jet Reynolds numbers are in the range of Re ∼ 3,500 – 27,000. Shadowgraphy is used to investigate the droplet sizes at the edge of the jets which are quantified using Hough transformation. The droplet size distribution results are observed to be bi-modal. The form of these distributions draw attention to prevalence of observed small satellite droplets being formed from the rupture of shear-layers in the flow. Results suggest that the radii of the small satellite droplets are independent of Re, while the average size of the large droplets is governed by the Weber number. High speed videos showing droplet shearing from large, submerged hydrocarbon jets into seawater will be presented.

3:48PM G16.00001 Towards Generalizable Data-driven Turbulence Model Augmentations. VISHAL SRIVASTAVA, KARTHIK DURAISAMY, University of Michigan, Ann Arbor — Reynolds Averaged Navier Stokes (RANS) models are based on a mix of physical and phenomenological ideas. Once a model structure is fixed, calibration is typically based on a few canonical flows, and as a result, models are often insufficiently accurate in many general applications. Data-driven techniques present the possibility of more accurate models of complex flows, though generalizability and robustness of such models is an open issue and the topic of the work. We address data-augmented turbulence models with a focus on enforcing consistency of the augmentations with the underlying model. Using a data-driven augmentation is consistent with and satisfies underlying physical laws (such as frame invariance) and known relationships (such as preserving the law of the wall in the large Reynolds number limit). These constraints are either imposed directly at the inference step or implicitly enforced by construction. Sample results are presented for equilibrium and non-equilibrium wall-bounded turbulent flows.

4:01PM G16.00002 A data-driven approach to modeling turbulent decay at non-asymptotic Reynolds numbers. MATEUS DIAS RIBEIRO, German Research Center for Artificial Intelligence (DFKI), GAVIN D PORTWOOD, Los Alamos National Laboratory, Los Alamos, PEETAK MITRA, University of Massachusetts, Amherst, TAN MIHN NYUGEN, NVIDIA Corporation, Santa Clara, BALASUBRAMANIA T NADIGA, MICHAEL CHERTKOV, Los Alamos National Laboratory, Los Alamos, ANIMA ANANDKUMAR, NVIDIA Corporation, Santa Clara, DAVID P SCHMIDT, University of Massachusetts, Amherst, NVIDIA TEAM, UMASS TEAM, LANL TEAM, DFKI TEAM — Dynamic modeling of turbulent processes away from asymptotic parameter limits is an active area of turbulence research. This study considers the transient modeling of the kinetic energy dissipation rate, an important component for turbulence closure models like k – c. While asymptotic analysis of the turbulent dissipation process effectively calibrates the model parameters at high and low Reynolds numbers, these calibrations are inaccurate at intermediate Reynolds with strong dependence on large-scale turbulence properties. In intermediate regimes, model tuning via data-driven regression has a leading-order effect on accuracy such that a purely data-driven approach is sensible. Here, we model the kinetic energy dissipation rate in decaying isotropic turbulence using a NeuralODE, a continuous-depth neural network which models continuous-time processes. After training a model using direct numerical simulations (DNSs) over a range of Reynolds numbers and large-scale turbulence initial conditions, we show that a purely data-driven approach to modeling turbulent dynamics via NeuralODEs provides an attractive solution to turbulence closure in non-idealized parameter regimes.
4:14PM G16.00003 A data-driven approach to modeling turbulent flows in an engine environment. PEETAK MITRA, University of Massachusetts Amherst, MATEUS DIAS RIBEIRO, German Research Center for Artificial Intelligence, DAVID SCHMIDT, University of Massachusetts Amherst — We build on work by Zare, Jovanovic, and Georgiou (JFM, vol. 812, 2017) to develop stochastically forced closure models for the mean flow equations of a turbulent channel flow. Given a subset of steady-state velocity correlations for a turbulent channel flow at a friction Reynolds number of 186, we formulate an inverse problem to determine the forcing statistics to the linearized model that provide consistency with DNS. The resulting stochastically forced linearized model is used to drive the mean flow equations in time-dependent simulations. This provides a connection to the mean velocity profile which perturbs the linearized Navier-Stokes dynamics. The feedback connection is implemented using a function that incorporates a two-way interaction between the mean and second-order statistics of the fluctuating velocity field. By analyzing conditions under which this feedback connection converges, we take a step toward the development of new classes of data-driven turbulence closure models.

4:27PM G16.00004 Toward data-driven stochastically forced turbulence closure models. ARMIN ZARE, University of Texas at Dallas, ANUBHAV DWIVEDI, University of Minnesota, MIHAIOLO JOVANOVIC, University of Southern California — We build on work by Zare, Jovanovic, and Georgiou (JFM, vol. 812, 2017) to develop stochastically forced closure models for turbulence environments. The present model combined with corrections to the shear-induced lift model by Tomiyama showed significantly improved results compared to existing models. In conclusion, both the evaluation and validation procedures showed that the present model based on ANN can estimate the bubble size reasonably well in turbulent bubbly flows.

4:40PM G16.00005 A data-driven approach to simulate turbulent bubbly flows using machine learning for modeling bubble size. HOKYO JUNG, YOUNGJAEE KIM, SERIN YOON, GANGWO HA, Dept. of Mechanical Engineering, Sogang University, JIN HO LEE, HYUNGMIN PARK, Dept. of Mechanical and Aerospace Engineering, Seoul National University, DONGJOO KIM, Dept. of Mechanical Engineering, Kumoh National Institute of Technology, JUNGHWOO KIM, Dept. of Mechanical System Design Engineering, Seoul National University of Science and Technology, SEONGWON KANG, Dept. of Mechanical Engineering, Sogang University — We build on work by Zare, Jovanovic, and Georgiou (JFM, vol. 812, 2017) to develop stochastically forced closure models for turbulence environments. The present model combined with corrections to the shear-induced lift model by Tomiyama showed significantly improved results compared to existing models. In conclusion, both the evaluation and validation procedures showed that the present model based on ANN can estimate the bubble size reasonably well in turbulent bubbly flows.

4:53PM G16.00006 Deep Neural Networks for Data-Driven Turbulence Models. ANDREA BECK, DAVID FLAD, CLAUS-DIETER MUNZ, University of Stuttgart — Machine learning methods and in particular deep learning via artificial neural networks have generated significant enthusiasm in the last years. Since these methods can provide approximations to general, non-linear functions by learning from data without a-priori assumptions, they are particularly attractive for the generation of subspace models for multi scale problems. In this presentation, we present a novel data-based approach to turbulence modelling for Large Eddy Simulation by deep learning via artificial neural networks. We first discuss and define the exact closure terms and generate training data from direct numerical simulations of decaying homogeneous isotropic turbulence. We then present the design and training of artificial neural networks based on local convolution filters to predict the underlying unknown non-linear mapping from the coarse grid quantities to the closure terms without a-priori assumptions. All investigated networks are able to generalize from the data and learn approximations. We further show that selecting both the coarse grid primitive variables as well as the coarse grid LES operator as input features significantly improves training results. Finally, we show how to construct a stable and accurate LES model from the learned closure terms.

5:06PM G16.00007 Generalized Non-Linear Eddy Viscosity Models for Data-Assisted Reynolds Stress Closure. BASU PARMAR, University of Colorado Boulder, ERIC PETERS, Ball Aerospace, KENNETH JANSEN, ALIREZA DOOSTAN, JOHN EVANS, University of Colorado Boulder — The prediction of turbulent flow is critical for the design and analysis of engineering systems. Unfortunately, Linear (LEV) and Non-Linear Eddy Viscosity (NLEV) models lack predictive capability in practical flow scenarios involving severe flow separation, secondary flows, and adverse pressure gradients. In this talk, we propose Generalized Non-Linear Eddy Viscosity (GNLEV) models for modeling the Reynolds stress tensor. In these models, we assume the anisotropic part of the Reynolds stress tensor is a function of the mean strain rate tensor, the mean rotation rate tensor, and the mean pressure gradient. This approach can be used to obtain a GNLEV model and thus can be used as a base for a second-order RANS model. For each of these basis functions, the coefficients associated with this expansion themselves are scalar functions of the invariants. The exact form of these coefficients is unknown and hence models must be introduced to obtain complete Reynolds stress closure. In this talk, we use a tensor-based feed forward neural network as a surrogate model to predict these coefficients. Numerical results illustrate the effectiveness of the proposed Reynolds stress closure approach.

5:19PM G16.00008 An S-frame Discrepancy Correction for Data-Driven Reynolds Stress Closure. AVIRAL PRAKASH, University of Colorado, Boulder, ERIC PETERS, Ball Aerospace, RICCARDO BALIN, KENNETH JANSEN, ALIREZA DOOSTAN, JOHN EVANS, University of Colorado, Boulder — Scale-resolving simulations demand large computational resources. Therefore, industry often relies on solving mean flow equations. This averaging leads to an unclosed term known as the Reynolds stress tensor. This closure problem is often addressed using linear eddy viscosity (LEV) models which assume alignment of the anisotropic part of the Reynolds stress tensor and mean strain rate tensor. However, the two tensors do not align for many turbulent flows, including those exhibiting flow separation. In this work, we present a strategy for modeling the discrepancy between the Reynolds stress tensor predicted by an LEV model and the actual Reynolds stress tensor. The strategy relies on learning the discrepancy components in the mean strain rate eigenframe. By intelligently selecting model inputs, we arrive at a model that is both frame and Galilean invariant. We can also ensure energy stability using a simple constraint on the diagonal terms of the discrepancy. To learn a computable model, we employ high fidelity DNS data and neural networks. Numerical results illustrate the effectiveness of our discrepancy modeling strategy. We finally discuss how to use model derived turbulence variables rather than DNS data in the learning process.
In this talk, we will present how to use the TBNN construction to model the turbulent scalar flux in a way that can be readily applied to a RANS framework. When a turbulent flow carries a scalar, such as heat or a contaminant, the turbulent scalar flux (a vector) needs to be modeled concurrently in the RANS framework. Only the prediction of a symmetric, traceless tensor (which is the case for the turbulence anisotropy) is required. In the scenario where a turbulent flow is represented by an invariant vector basis, the tensorial turbulent diffusivity which is predicted from extrapolating while the simulation iterates to convergence. The training and testing sets include the flow over an asymmetric bump and a 180-degree U-bend. When applied to the U-bend, the TBNN-RANS improves predictions of the mean velocity deficit and eliminates unphysical secondary flows predicted by the baseline k-omega RANS model. After quantifying its performance, we compare our formulation to previous algebraic stress models and the optimal basis representation derived by Gatski and Jongen (2000).

4:01PM G17.00002 Tensor Basis Neural Networks for Turbulent Scalar Flux Modeling

The Tensor Basis Neural Network (TBNN) model developed by Ling et al. (2016) has shown great promise to improve the momentum equations in Reynolds-averaged Navier-Stokes (RANS) solvers. It uses physical insight together with machine learning paradigms to embed rotational invariance into a deep neural network, and then predicts a turbulence anisotropy tensor that obeys this property. The original formulation allows only the prediction of a symmetric, traceless tensor (which is the case for the turbulence anisotropy). In the scenario where a turbulent flow carries a scalar, such as heat or a contaminant, the turbulent scalar flux (a vector) needs to be modeled concurrently in the RANS framework. In this talk, we will present how to use the TBNN construction to model the turbulent scalar flux in a way that can be readily applied to a RANS solver. Manipulation of the appropriate invariant vector basis leads to a form with a general, tensorial turbulent diffusivity which is predicted by the deep neural network at test time. We apply this model to an inclined jet in crossflow and obtain significant improvement in the mean scalar concentration prediction.

4:14PM G17.00003 CFD-ready Turbulence Models from Gene Expression Programming: Concepts

The gene expression programming (GEP) method is applied to develop Reynolds-averaged Navier-Stokes (RANS) models via symbolic regression. The candidate models, represented by strings of genes competing and evolving in the training, can be interpreted as explicitly given equations. Thus, the resulting model, which minimizes the cost function, can be directly implemented into RANS solvers. Based on the advantages of the GEP method, two training strategies have been proposed to develop CFD-ready RANS models. In the first framework called frozen-training, the models are trained to fit high-fidelity Reynolds stress data. In the second approach, called CFD-driven training, the fitness of candidate models is evaluated by running RANS calculations in an integrated way. Both methods have been applied to model development for wake mixing in turbomachines. New models are trained based on a high-pressure turbine simulation data and embedded within a RANS code so that its predictions are agnostic to errors in any baseline RANS solution. A Gaussian closure, while being 400 times cheaper than the high-fidelity simulation.

1This research used resources of the Oak Ridge Leadership Computing Facility, which is a DOE Office of Science User Facility supported under Contract DE-AC05-00OR22725.

The existing turbulence closure in URANS, in addition to being a poor representation of the turbulence length scales also accounts for the deterministic shedding scales twice: through the closure and the scale resolution. We propose an alternative non-linear closure, which is built only for the stochastic scales, i.e., devoid of the shedding scales, allowing URANS to resolve the deterministic unsteadiness. The closure is obtained from a novel symbolic regression algorithm: Gene Expression Programming (GEP), which generates a tangible equation for the modelled anisotropy. Using a high-fidelity dataset as reference, the stochastic component of the anisotropy is extracted by triple decomposing the data, which is subsequently used by GEP to produce the new closure. Once obtained, the closure can be used in isolation within URANS as it does not rely on high-fidelity data anymore. The approach is demonstrated using a zero pressure gradient turbulent wake as the reference dataset. The obtained closure was tested on 6 unseen cases, including pressure gradients, and the model significantly outperforms the existing closure, while being 400 times cheaper than the high-fidelity simulation.

by using deep neural networks, MUHAMMAD IRFAN ZAFAR\textsuperscript{1}, Virginia Tech, JIEQUN HAN\textsuperscript{2}, Princeton University, HENG XIAO\textsuperscript{3}, Virginia Tech — Recent advances in machine learning techniques have enabled researchers to explore data-driven turbulence models as attractive alternatives to traditional algebraic or PDE-based models. However, current data-driven models are all based on local mapping and thus are only applicable to equilibrium turbulence (as with the eddy-viscosity model and algebraic stress models). In this work, we present a PDE-inspired deep neural network architecture based on non-local mapping, which will be used to discover a turbulent constitutive relation from data. Such a network-based representation retains the non-local transport physics embodied in the Reynolds stress transport equations but avoids explicit modeling of individual terms. Furthermore, the neural network is devised to be frame-independent, which is a basic requirement of all constitutive models. Simple illustrative examples are presented to demonstrate the merits of the proposed framework.

5:06PM G17.00007 Deep learning based sub-grid scale closure for LES of Kraichnan turbulence\textsuperscript{1} — SIURAJ PAWAR, OMER SAN, School of Mechanical & Aerospace Engineering, Oklahoma State University, Stillwater, Oklahoma - 74078, USA., ADIL RASHEED, Department of Engineering Cybernetics, Norwegian University of Science and Technology, N-7465, Trondheim, Norway. — Performing high-fidelity simulations of large scale multiscale flow problems that resolves fine spatiotemporal features is computationally intractable. Performing eddy simulation (LES) techniques at reducing the computational resources by resolving large scales of the flow and the effect of small scales is modeled. In the present work, we put forth data-driven sub-grid scale closure models for LES of two-dimensional Kraichnan shear stress. The shear stress without averaging in the homogeneous direction(s), which is often adopted for the use of the dynamic Smagorinsky model. The present NN model is applied to a higher Reynolds number ($Re \approx 720$) with the model trained at lower Reynolds number. The results also show good agreements with those of filtered DNS data.

5:19PM G17.00008 Improving linear embedding of complex nonlinear flow dynamics\textsuperscript{1} — NIKOLAUS ADAMS, LUDGER PAEHLER, Technical University of Munich — We propose an improvement on the concept of linear embedding of nonlinear flow dynamics by a Koopman-mode encoding network. A solution representation of approximate Koopman modes enables a linear estimation of the time evolution on a reduced number of degrees of freedom. Lusch et al., Deep learning for universal linear embeddings of nonlinear dynamics. Nature Communication, 2018, have proposed an encoder-decoder deep learning approach of approximate Koopman projection, and have demonstrated application feasibility for dynamical systems with continuous spectra. The most complex flow considered by Lusch et al. is that of low-Reynolds-number incompressible 2D cylinder flow. The objective of our work is to obtain a better representation of latent dynamics in order to represent significantly more complex flow dynamics. The concept is to improve on the auto-encoding capability of the deep learning approach with a probabilistic objective and by including input information. We demonstrate feasibility of the approach for broadband flow dynamics such as generated by 3D Taylor-Green vortex-flow transition. Also, we will consider the representation of compressibility effects in oscillating gas-bubble dynamics.

4:01PM G18.00002 Turbulent intensity Enhancement by gaps in submerged Canopy Flows , HAYOON CHUNG, TRACY MANDEL, MARGARITA DRONOV, JEFFREY KOSEFF, Stanford University — Canopies such as seagrass alter their dynamical environment by impacting the flow and turbulent structures. However, unlike well-studied systems in which fully developed boundary layers encounter homogenous and uniform canopies, many aquatic canopy systems display patchiness, e.g., gaps and clearings, that impact the flow, and also interact with velocity fields that are still developing. Therefore, what are the impacts of gaps, both locally and at the canopy scale? We conducted experiments in a recirculating flume with a model vegetation canopy. The canopy is broken up by gaps of varying lengths, and velocities and turbulence observations show the decay of the mixing layer in the gap before it re-enters the downstream canopy segment. The ML decays into a more linear profile, and spreads more shear and turbulent intensities throughout the water column, particularly higher up away from the canopy roughness. Therefore, when compared to an uninterrupted homogenous canopy, the fragmented canopy experiences enhanced turbulent energy at various locations along the canopy. We studied the impact of gap lengths on the extent of turbulence enhancement, and the extent to which the disturbance propagates along the canopy.

4:14PM G18.00003 Influence of plant flexibility on turbulent aquatic canopy flow , SIDA HE, LIAN SHEN, University of Minnesota — Aquatic plant plays an important role in the hydrodynamics of aquatic environments, such as river, lake, and ocean. We have simulated the turbulent flow in submerged aquatic canopy with plant flexibility varying from absolute rigid to extremely flexible. Different from the classical approach of modeling the hydrodynamic effect of canopy as a volume drag force, we resolved the hydrodynamic effect of every plant by an immersed boundary method. Our approach has two benefits: (1) the interaction between the turbulent flow and canopy can be inspected directly; (2) a priori constant drag coefficient is not required. We found that the value of plant flexibility on the turbulent flow and canopy waving motion, i.e., monami. For all canopy flexibility, the velocity profile is self-similar in the mixing layer, though it does not completely follow the hyperbolic tangent profile of pure mixing flow. Our comparison of the mean momentum transport in the flexible and rigid canopy shows the significance of Reynolds stress and dispersive flux in the flexible canopy. We also studied the dispersion relation of monami and found that the wave speed of the high-wavenumber component depends on the plant flexibility.

4:27PM G18.00004 Vibrationally enhanced energy fluctuation in compressible isotropic turbulence with thermal non-equilibrium , QINMIN ZHENG, JIANCHUN WANG, MINPING WANG, SHIYI CHEN, Department of Mechanics and Aerospace Engineering, Southern University of Science and Technology; HUI LI, School of Power and Mechanical Engineering, Wuhan University — The vibrationally enhanced energy fluctuation of compressible isotropic turbulent flows in vibrational non-equilibrium is investigated numerically at turbulent Mach numbers of 0.44 and 1.09, focusing on the effect of the characteristic vibrational relaxation time on statistical features of the dissipation/production components of vibrational energy fluctuation. The dissipation/production of vibrational energy fluctuation might result from effects of dilatation, thermal diffusion and vibrational relaxation. The dissipation component due to thermal diffusion always suppresses the vibrational energy fluctuation in both of compression and expansion regions for the weakly and highly compressible turbulences; but its effect is insignificant comparing to other two components. For the weakly compressible turbulence, the dissipation/production of vibrational energy fluctuation mainly comes from effects of dilatation and vibrational relaxation when the characteristic vibrational relaxation time is small; and the vibrational relaxation component loses its significance gradually with the increase of characteristic vibrational relaxation time. For the highly compressible turbulence, both of the dilatation and vibrational relaxation effects play an important role in the dissipation and production of vibrational energy fluctuation.

4:40PM G18.00005 Enhanced Drag Reduction by High Mach Number Streaming1 , TAIPISH AGARWAL, BENI CUKUREL, IAN JACOBI, Technion — Significant drag reduction for a laminar boundary layer is predicted for high Mach number, travelling-wave flow actuation. Historically, low Mach number, temporal or standing waves were used to modify a base laminar flow by Stokes streaming. Predictions for the associated drag reduction were based on asymptotic, high frequency approximations of the governing momentum balance. We present a numeric solution of the full momentum balance for the streaming flow, based on Lin’s Reynolds decomposition analysis, which allows for examination of the complete range of forcing frequencies. The solution also provides for analysis of travelling wave actuation, which is better suited for practical implementation in boundary layers and channels. The streaming-induced drag reduction is studied as a function of the Mach number, Reynolds number, forcing amplitude, and frequency. In particular, high Mach number, high frequency travelling waves are predicted to produce significant laminar drag reduction. 1United States - Israel Binational Science Foundation Grant Number 2016358

4:53PM G18.00006 Laminar flow in planar Tee joints , MARCOS VERA, Universidad Carlos III de Madrid, GUSTAVO A. PATIO, Instituto Tecnologico Metropolitano, Medellin, IMMACULADA IGLESIAS, Universidad Carlos III de Madrid — We present a numerical investigation of the laminar flow in planar Tee joints, a canonical flow of interest for the thermal-hydraulic design of oil power transformer windings. The steady, constant property flow in planar Tee joints is computed numerically by integrating a non-dimensional formulation of the Navier-Stokes equations with fully developed upstream and downstream boundary conditions. The analysis assumes a straight-through configuration in which the straight duct holds flow in the same direction before and after the junction, whereas the flow from the side branch can combine with the incoming flow or divide from it. We present a description of the flow patterns that emerge in both cases for a full range of mass split ratios, $0 \leq \alpha \leq 1$, several values of straight duct to side branch width ratios, $1 \leq \beta \leq 3$, and Reynolds numbers of the common branch in the range $10^3 \leq \text{Re} \leq 2 \times 10^4$. Flow maps for planar Tee joints are presented, showing the existence of different regions in the $(\text{Re}, \beta)$-plane that exhibit different number and location of recirculation zones. From the pressure distribution, secondary loss coefficients are computed and used to fit pressure loss correlations useful for pipe-network modelling of oil power transformer windings.

5:06PM G18.00007 Considering spatial inhomogeneities in forest canopies , RYAN SCOTT, HAWWA FALIH, SARAH SMITH, NASEEM ALI, JULIAAN BOSSUYT, Portland State University, MARC CALAF, University of Utah, RAUL CAL, Portland State University — Forest canopies serve a key role in determining regional climate and modify terrestrial surface roughness. Forests are typically considered large areas of contiguous roughness elements. While forest composition exists in a state of constant flux, human activities impose an ordered arrangement on local canopy structure. In particular, logging and development produce non-homogeneous patterns of canopy patches separated by regular gaps. To quantify the role of these patterns on the canopy sublayer, a series of wind tunnel experiments were performed with a scaled model forest canopy. The model forest was constructed of multiple patches spanning the width of the wind tunnel. Each patch was comprised of model conifers with a total height of 10 cm and cone diameter of 4 cm. Individual trees were realized by an interconnected reticulated foam canopy layer attached to evenly spaced tree trunks. Particle image velocimetry measurements were collected above the canopy and within gaps for both homogeneous and non-homogeneous canopies. From these measurements, the influence of non-homogeneous canopy patterns is quantified by computing relevant mean statistics and flow structures. In addition, the implications for local effects and land management practices will be discussed in presentation.
from the problem of the typical tilted spectral distribution. Besides, the ANNMM model predicts the PDFs of SGS energy flux much better than the prediction of spectra of velocity and temperature, which almost overlap with the filtered DNS data while the DSM and DMM models suffer from a posteriori almost recovers the average values of the SGS energy flux and SGS energy flux conditioned on the normalized filtered velocity divergence. In an attempt to simulate the turbulent flow over rough walls, the surface roughness is also filtered due to the relatively large grid spacing. The sub-grid-scale roughness can have a great impact on the turbulent flow, and must be properly modeled. Although some efforts have been made, the LES of turbulent flow over rough walls still remains an open problem. Typically, the roughness effect is modeled by prescribing the instantaneous stress on the first grid point above the wall according to the equilibrium log-law assumption. However this method tends to overestimate the mean stress.

Instead of that, we propose that the effect of surface roughness can be effectively simulated by constraining the near-wall Reynolds stress, which can have a great impact on the turbulent flow, and must be properly modeled. from the Beaufort Gyre Exploration program. Revealing the non-linear resonance within our system. Future work will consider the effects of an external force and incorporate observations.

Our key analysis tool is a novel coordinate rotation, rotating our Boussinesq equations into the space of the waves and so resonance of IGWs. Our work is motivated by the phenomena of layer formation in the upper Arctic Ocean, which prevents the ice packs from the long-lived nature of layers in non-rotating stably-stratified flows and discuss whether our results support the idea that internal gravity waves stratified fluids.

The characteristics of the internal wave field are also altered on varying $\epsilon$ of $R$. The spatial and temporal variability of $\omega$ is systematically varied (by varying $U$), even when normalized with $U_m/D$ (where $U_m = U_c + U_1$ is the maximum barotropic velocity attained by the flow), increases with increasing $R$. The spatial and temporal variability of $\omega$ during the tidal cycle is quantified to further understand the behavior of $\epsilon$. Analysis of vortex dynamics reveal the formation of vortex dipoles during flow reversal, triggered by strong lateral flow and upstream acceleration of fluid in the recirculation zone. The characteristics of the internal wave field are also altered on varying $R$.

4:53PM G20.00006 Subsurface Suppression of Turbulence in the Bay of Bengal\(^1\). RAMA GOVINDARAJAN, RITABRATA THAKUR, International Centre for Theoretical Sciences Bengaluru, EMILY L SHROYER, CÉOAS, Oregon State University, J THOMAS FARRAR, ROBERT A WELLER, Woods Hole Oceanographic Institution, JAMES N MOUM, CEOAS, Oregon State University — Quantifying the degree of turbulence and mixing, in an ocean is important to understand how it responds to surface forces and distributes subsurface fluxes. The northern Bay of Bengal is highly salinity-stratified due to the discharge of numerous rivers and precipitation. From a year-long dataset of subsurface turbulent fluxes we show that it is not only surface forcing, but its interplay with an evolving complex subsurface stratification that determines the seasonality in turbulence. We observe a months-long suppression of turbulence below 40m when low-salinity water is present in the topmost layer (Thakur et al. “Seasonality and Buoyancy Suppression of Turbulence in the Bay of Bengal.” Geophysical Research Letters 46.8 (2019): 4346-4355.), in spite of high winds. An implication is that the low mixing with deeper colder water can provide a heat source for tropical cyclogenesis. The stability reasons for this suppression will be discussed.

5:06PM G20.00007 Predicting Interannual Variability of Climate using Deep Learning\(^1\), BALASUBRAMANYA NADIGA, Los Alamos National Lab, CHANGLIN JIANG, AMIR FARIMANI, CMU — Predictability of climate over the interannual to decadal timescale (near term) is controlled by both natural variability related predictability and external-forcing related predictability. Given that the field of near-term prediction of climate is in a nascent stage of development, we examine a deep learning approach to the problem. Preliminary work using a Long Short-Term Memory network architecture with added encoding and decoding is found to be capable of predicting an Earth System Models leading modes of global temperature variability with prediction lead times of up to a year. Related issues and further extensions are discussed.

5:19PM G20.00008 Bayesian calibration of global climate models using infrasound events, CHRISTOPHE MILLET, CEA & CMLA, ENS Paris-Saclay, France, FRANCOIS LOTT, LMD, ENS Paris, France, ALVARO DE LA CAMARA, Universidad Complutense de Madrid, Spain — While stochastic parameterizations in Global Climate Models (GCMs) are promising for improving longstanding climate predictions, there is no consensus regarding the values of tunable parameters. In this work, we propose a Bayesian hierarchical approach to calibrate the input parameters of a stochastic multiwave gravity wave (GW) scheme, which is currently in use in the LMD GCM. The GW field is obtained as a combination of individual wavepackets, whose horizontal wavenumber, direction and phase speed are chosen randomly. These parameters are inferred using ground-based infrasound records as tracers of small-scale GW variability. In a sense, the acoustic signals are “back propagated” to adjust the GW sources on a daily basis, using for this a WKB approximation of the Taylor-Goldstein equation to represent the upward-propagating GWs. The method is applied using acoustic signals observed at the Norwegian station in August-September every year. These signals are known to be generated by the well-characterized daily ammunition destruction explosions that occur at the Hukkakero site, in northern Finland. The performance of the method is demonstrated by comparing the updated climatology and variability of the middle atmosphere with the reanalysis provided by the European Centre for Medium-Range Weather Forecasts.

Sunday, November 24, 2019 3:48PM - 5:32PM — Session G21 Drops: Impacts with Liquids II 603 - Omar Matar, Imperial College London

3:48PM G21.00001 Streamlined air-cavities formed by non-superhydrophobic spheres impacting water\(^1\), ADITYA JETLY, IVAN URIEV VAKARELSKI, SIGURDUR THORODDSEN, King Abdullah University of Science and Technology — The formation of a stable and streamlined gas cavity following the impact of a sphere on a deep pool, is a recently observed phenomenon\(^2\), which shows motion at near-zero drag. This was shown for both Leidenfrost as well as superhydrophobic spheres. We now extend these results by demonstrating that both metallic and non-metallic spheres, with contact angles between \(30\) and \(120\), can also form stable streamlined cavities, when they are dropped from sufficient height above the pool surface, ranging from \(2\) to \(4\) m. The stable streamlined cavity is attached to the sphere surface just above the equator, instead of being wrapped completely around it. This sphere-with-attached-cavity exhibits slightly narrower shape, but retains the near-zero drag and the free-fall velocity is in compliance with the Bernoulli Law of potential flow\(^2\).\(^1\)Vakarelski et al., Science Advances, 3: e1701558 (2017). \(^2\)Vakarelski*, Jetly & Thoroddsen, Soft Matter, 10.1039/C9SM01025D (2019).

4:01PM G21.00002 How nose curvature affects splashing, JESSE BELDEN, Naval Undersea Warfare Center, MATTHEW JONES, Utah State University, Dept. of Mechanical & Aerospace Engineering, AREN HELLUM, ANTHONY PAOLERO, Naval Undersea Warfare Center, TADD TRUSCOTT, Utah State University, Dept. of Mechanical & Aerospace Engineering — The splash and air cavity formation following the impact of a disk on a free surface are well-documented. Such events are characterized by a sub-surface air cavity and an above surface splash crown that ultimately domes over and seals. If slight curvature is given to the face of the disk, however, these phenomena can change quite dramatically, even resulting in cases that suppress cavity formation. In this talk, we examine the effect of nose curvature on the splash and cavity physics and suggest mechanisms responsible for the observed differences. Furthermore, we directly measure body accelerations in order to estimate instantaneous forces, and relate these measurements to high speed images of the cavity and splash phenomena.
4:14PM G21.00003 Impact of a drop containing a bubble onto a liquid surface, SIQI ZHU, MARIE-JEAN THORAVALE, Xi’an Jiaotong University — We study experimentally the dynamics of a drop containing a bubble falling onto a liquid pool of the same liquid. We first propose an experimental setup to control the formation of this compound drop, controlling its stable formation and the volume of the air bubble. Then we systematically vary the falling height to change the impact velocity. We identify three different regimes by using a dual view high-speed imaging setup to observe the dynamics above and below the pool surface. At low impact velocity, the bubble is pushed into the pool. Above a critical impact velocity, the bubble bursts during the impact, releasing the air bubble before it could be entrapped into the pool. Finally, for higher impact heights, the air drag forces the bursting of the bubble during its falls, before impacting onto the liquid pool. We vary the liquid properties and bubble size to understand these two transitions, and propose some physical explanations.

4:40PM G21.00005 Numerical Simulations of Drop Impact on Surfactant-Laden Interfaces1, RICHARD CRASTER, ASSEN BACHTVAROV, LYES KAHOUDJ, CRISTIAN CONSTANTE-AMORES, OMAR MATAR, Imperial College London — The impact of drops on solid and fluid substrates is accompanied by rich phenomena that have been the source of fascination for decades. Recent experimental work (Che and Matar, Langmuir, 33, 43, 12140-12148, 2017) has investigated the effect of surfactants on the phenomenon of “crown” splashing and found that they affect significantly the propagation of capillary waves, the evolution of the crown, and the formation of secondary droplets. In this work, we employ three-dimensional direct numerical simulations to examine drop impacts on thin films in the presence of surfactants. We use a hybrid interface-tracking/level-set method for the interfacial dynamics coupled to a convective-diffusion equation for the surfactant concentration to carry out the computations. We vary different surfactant properties (i.e. diffusion, elasticity, and solubility) to study their effect on the phenomena accompanying the drop impact.

5:06PM G21.00007 Drop-on-drop Impacts of Complex Liquids: the case of blood1, FUJUN WANG, VANESSA GALLARDO, STEPHEN MICHIELSEN, TIEGANG FANG, North Carolina State University — The interaction of an impacting drop with a sessile drop has received rising attention due to its importance in many applications. Most of the prior work focused on water. In this study, the drop-on-drop impact of blood on a glass surface with varying impact velocities was experimentally investigated. Through a fine adjustment, we obtained a complete regime map, including the bouncing, coalescing, jetting, crown formation, fingering, and film breakup. We quantified the maximum spread diameter (Dm) and the final contact diameter on the surface (Df) after drop-on-drop impact. The measurement of Dm was compared with a model for water and modifications were added for the non-Newtonian effects. For the latter, we found a critical Weber number (We), below which Df will remain the same as the sessile drop. Beyond We, an increase of Df was found to be caused by the collapse of the crown. We finally identified the difference between the fingering and film breakup. The film breakup was generated by the off-center impact during the spreading phase while the fingering breakup took place for the center impact during the collapsing process. The presented cases can well mimic the consecutive impact of blood drops in forensic science.

The role of humidity and pressure in preserving superhydrophobicity for droplet impact\(^1\), HENRY LAMBLEY, THOMAS SCHUTZIUS, DIMOS POULIKAKOS, ETH Zürich — The design of robust superhydrophobic surfaces for impacting water droplets is typically achieved by creating surface structures with capillary (anti-wetting) pressures greater than that of the incoming droplet (dynamic, water hammer). Recent work has focussed on how competition between compression and drainage of air within the surface texture dictates the evolution of the intervening air layer between droplet and substrate and its role in promoting impalement under ambient conditions through local increases in the droplet curvature. However, little consideration has been given to the influence of the intervening air layer composition, and compressibility effects, when departing from ambient conditions on the impact outcome. Here, we explore the limits of the working envelope for robust superhydrophobic surfaces by varying the ambient pressure and water vapour content. By testing rationally engineered materials with both micro and nanoscale features, we are able to provide additional design constraints and propose solutions for future applications of superhydrophobic and iceophobic technologies across a broad range of environmental conditions.

Multilayered synthetic feathers for enhanced underwater superhydrophobicity \(^1\), ZAARA DEAN, FARZAD AHMADI, VIVERJITA UMASHANKAR, Virginia Tech, BRIAN CHANG, Temple University, SUNGHWAN JUNG, Cornell University, JONATHAN BOREYKO, Virginia Tech — Submerged superhydrophobic surfaces can dramatically reduce hydrodynamic drag and bio-fouling, but the enabling air pockets are prone to irreversible collapse. Inspired by ducks, we demonstrate that air pockets within stacked layers of porous superhydrophobic feathers can withstand up to five times more water pressure compared to a single feather. In addition to natural duck feathers, the multilayered effect was replicated with synthetic feathers created by laser cutting micrometric slots into aluminum foil and imparting a superhydrophobic nanostructure. The mechanism for the multilayered enhancement is the more tortuous pathway required for water impalement, which serves to pressurize the enclosed air pockets. This was validated by a probabilistic impalement model and also by filling the feathers with an incompressible oil, rather than air, to suppress the multilayered effect.

Surfactant droplets on hydrophobic microstructures\(^1\), PEICHUN AMY TSAI, NADIA SHAROT, MASOUD B. BIGDELI, JANET ELLIOTT, University of Alberta — Surfactantsamphiphilic molecules can readily adsorb at interfaces. Their presence can destroy the useful, gas-trapping (Cassie-Baxter, CB) wetting state of a drop sitting on a superhydrophobic surface. Here, we examine how surfactants alter the wetting state and contact angle of aqueous drops on hydrophobic microstructures of different surface roughness (r) and solid fraction (\(\phi\)). Experimentally, at low surfactant concentrations (\(C_s\)), some drops attain a homogeneous wetting state (Wenzel, W), while other drops are in the CB state. In contrast, all of our high \(C_s\) drops attain the Wenzel state. To explain this observed transition, we develop a thermodynamic free energy analysis and find that, theoretically, for our surfaces the W state is always thermodynamically preferred, while the CB state is metastable at low C, consistent with experimental results. We further provide a beneficial blueprint for stable CB, gas-trapping states for applications exploiting superhydrophobicity.

Dropwise Condensation on Hierarchical Uncoated Metallic Surfaces, DANIEL OREJON, University of Edinburgh, I2CNER, ALEXANDROS ASKOUNIS, University of East Anglia, DANIEL ATTINGER, Iowa State University, YASUYUKI TAKATA, I2CNER, Kyushu University — Dropwise condensation is receiving increasing attention in the past decade. Traditionally, for the fabrication of hydrophilic and superhydrophobic surfaces able to perform in a dropwise condensation manner, the application of a conformal hydrophobic coating was required. In this work, we demonstrate that by passive exposure of our metallic hierarchical micro- and nano-structured copper oxide surface resembling the wetting behavior of a lotus leaf, superhydrophobicity and dropwise condensation can be achieved. The change in wettability from hydrophilic to hydrophobic is due to the adsorption of volatile organic compounds present in the ambient. On contrast, on a similar copper etched surface without copper oxide nanostructures resembling the wetting behavior of a rose petal, filmwise is the final condensation reported. Experimental observations at the micro- and at the macro-scale coupled with droplet morphology and surface coverage analysis, as well as a surface energy analysis are presented to support the different condensation behavior. We conclude on the feasibility of dropwise condensation by the coupling mechanisms of surface structure and hydrocarbon adsorption without the need for a manmade hydrophobic coating. The authors gratefully acknowledge WPI-I2CNER and ThermoSmart for their support.
4:40PM G22.00005 Quantification of Wind-Driven Water Droplets over Surfaces with Different Wettabilities, HUI HU, ZICHERN ZHANG, LIQUN MA, Iowa State University — In the present study, a comprehensive experimental study is performed to quantify the transient runback behavior of water droplet/rivulet flows as driven by boundary layer winds over the surfaces of test plates with different wettabilities. The experimental study is conducted in a low-speed wind tunnel available at Iowa State University (ISU-IRT). A suite of advanced flow diagnostic techniques, which include high-speed photographic imaging, digital image projection (DIP), particle image velocimetry (PIV), are used to quantify the transient runback behavior of water droplets over test plates as driven by the boundary layer winds. Water droplets with their volumes changing from 10 to 100 µL are tested under different incoming wind speeds. In addition to measuring the airflow velocity field around the wind-driven water droplets/rivulets, dynamic shape changes and stumbling runback motion of the water droplets/rivulets are also measured in real time in terms of water film thickness distribution, contact line moving velocity and wet surface area over the test plates with different wettabilities. The findings derived from the present study would be very helpful to gain a better understanding about the important microphysical process, which could lead to improvements of icing accretion models for more accurate prediction of ice formation and accretion process as well as the development of effective anti-/de-icing strategies for aircraft icing mitigation. /abstract- Zichen Zhang, Liqun Ma

4:53PM G22.00006 Out-of-Plane Self-Propulsion of Droplets on Heated Lubricant-Impregnated Surfaces, SUSMITA DASH, Indian Institute of Science, JOLET DE RUITER, Wageningen University, KRIPA VARANASI, Massachusetts Institute of Technology, SUSMITA DASH TEAM, JOLET DE RUITER TEAM, KRIPA VARANASI TEAM — The dynamics of droplets on heated surfaces is crucial for heat transfer applications such as spray cooling. Here we report on the behavior of millimetric water droplets on heated liquid impregnated surfaces (LIS) that are stable at high temperatures. Next to a gentle in-plane hopping motion, droplets can demonstrate one of two vigorous behaviors — at temperatures far below the typical Leidenfrost temperature: either a trapped gas bubble expands to “blow-up” the droplet into a thin liquid shell, or the droplet “jumps” out-of-plane. While the in-plane motion of the droplet is on the order of 10 mm/s, the droplet is propelled vertically upwards to several times its diameter at a velocity of approximately 200 mm/s. We present the mechanics underlying this behavior of droplets, which is specific to lubricant-impregnated surfaces and crucially depends on the thermodynamic state of the impregnating liquid.

5:06PM G22.00007 Impact-induced jets of highly-viscous liquids using a simple syringe1. HAJIME ONUKI, KYOTA KAMAMOTO, YOSHIYUKI TAGAWA, Tokyo University of Agriculture and Technology — In 3D manufacturing, the increment of the executable liquid viscosity is crucial. This study introduces a new method for generating a jet of highly viscous liquid. In our method, a syringe is partially filled with a liquid. The meniscus near the tip of the syringe initially has a concave shape, which induces the flow-focusing effect during the jet formation. The jet emerges when the short-time impact (e.g., collision with the rigid floor) is applied. Remarkably, the highly viscous liquid up to 1,000 cSt is ejected as a liquid jet. The speed of the jet can be controlled by the liquid height inside the syringe. We discuss the reason why the new method can eject the highly viscous liquid based on our previous theory (Onuki et al., Phys. Rev. Applied 2018). We find that, thanks to the geometrical relation, the gradient of the pressure impulse (time integration of the pressure) inside the tip of the syringe is strongly increased, resulting in increasing the jet speed.

Sunday, November 24, 2019 3:48PM - 5:32PM –
Session G23 General Fluid Dynamics: Viscous Flows 605 - Neil Balmforth, University of British Columbia

3:48PM G23.00001 Experiments and analysis of viscous flows in bistable elastic channels, OFEK PERETZ, Faculty of Mechanical Engineering, Technion - Israel Institute of Technology, ANAND MISHRA, ROBERT SHEPHERD, Organic Robotics Laboratory, Cornell University, Ithaca, New York, AMIR D. GAT, Faculty of Mechanical Engineering, Technion - Israel Institute of Technology. — COLLABORATION — We present experimental results of viscous fluid propagating into a slender channel with bi-stable cross-section shape, emanating from an upper surface which is a compressed curved elastic sheet. During the propagation of the liquid into the channel, the surface snaps from one stable shape to the other, and a moving front is observed. This front includes wrinkling of the elastic surface, and is shown to provide a stable transition between the two stable shapes of the channel. The viscous flow is analyzed via applying the lubrication approximation and examining self-similarity. For the case of constant inlet pressure, the propagation rate of the transition region is presented for various physical limits. Good agreement is obtained between the experiments and analysis.

4:01PM G23.00002 Hollow-Fiber Microfiltration Systems: Stokes Flow Solution in a Semi-Infinite Channel with Permeable Walls, FRANCESCO BERNARDI, NICHOLAS G. COGAN, M. NICHOLAS J. MOORE, Florida State University — Most wastewater management facilities aimed at water purification in the United States utilize hollow-fiber microfiltration. In these systems, pipes are split into thousands of micrometer-scale capped tubes with permeable walls. As wastewater flows through the filter, foulants are captured by the membraned walls allowing clean water to exit. Understanding the fluid dynamics is a fundamental step towards controlling the fouling process and enhancing the efficiency of microfiltration. We investigate the flow of wastewater through a single hollow-fiber tube. Starting from an infinite channel with permeable walls, we solve the Stokes flow problem in the channel interior for all permeability regimes. Then, we generalize the result to a semi-infinite channel with permeable walls capped at one end to mimic a single hollow-fiber system. Comparison with experiments and future directions will be discussed.

4:14PM G23.00003 Three-dimensional Hiemenz Stagnation-Point Flows, PATRICK WEIDMAN, Department of Mechanical Engineering — A modification of Hiemenz’ two-dimensional outer potential stagnation-point flow of strain rate $\alpha$ is obtained by adding periodic radial and azimuthal velocities of the form $br \sin 2\theta$ and $br \cos 2\theta$, respectively, where $b$ is a shear rate. This leads to the discovery of a new family of three-dimensional viscous stagnation-point flows depending on the shear-to-strain rate ratio $\gamma = b/\alpha$ that exist over the range $-\infty < \gamma < \infty$ with reflectional symmetry about $\gamma = 0$. Numerical solutions for the wall shear stress parameters and the displacement thicknesses are given and compared with their large-$\gamma$ asymptotic Behaviors. Sample similarity profiles are also presented.
E. coli, the form of helices in viscous shear flows migrate across streamlines as a result of their chiral shape and the shear flow. This chirality-induced.TESSER, ESPCI Paris, ANDREAS ZTTL, TU Wien, JUSTINE LAURENT, OLIVIA DU ROURE, ANKE LINDNER, ESPCI Paris — Particles in helical morphologies. Our theory highlights why helical coiling is so ubiquitous in strain-dominated flows.

The origin of helical buckling, we also perform a weakly nonlinear stability analysis. Following a linear Euler buckling regime induced by compressive stresses, unstable planar modes are shown to interact in the presence of geometric nonlinearities and spontaneously give rise to three-dimensional helical morphologies. Our theory highlights why helical coiling is so ubiquitous in strain-dominated flows.

1Leverhulme Trust

4:40PM G23.00005 Helical buckling of flexible filaments in viscous flow. BRATO CHAKRABARTI, University of California, San Diego, YANAN LIU, Northwest University, Xi'an, China. JOHN LAGRONE, RICARDO MARTÍNEZ, LISA FAUCI, Tufts University, OLIVIA DU ROURE, ESPCI, Paris, DAVID SAINTILLAN, University of California, San Diego, ANKE LINDNER, ESPCI, Paris — Helical morphologies of slender structures in flow are generic and have been observed in various experiments and manufacturing processes over a range of length scales. In contrast with the classical helical buckling of elastic rods that requires application of end moments, helical buckling of freely suspended filaments is a spontaneous symmetry breaking induced by distributed viscous forces. In a step towards elucidating this phenomenon, we demonstrate using microfluidic experiments that actin filaments first buckle in compressional flow due to viscous stresses and subsequently form coiled conformations, and two complementary sets of simulations in different geometries also reveal the same. The radius of the emerging helices is found to be independent of filament length, which we explain using a scaling law. To explain the origin of helical buckling, we also perform a weakly nonlinear stability analysis. Following a linear Euler buckling regime induced by compressive stresses, unstable planar modes are shown to interact in the presence of geometric nonlinearities and spontaneously give rise to three-dimensional helical morphologies. Our theory highlights why helical coiling is so ubiquitous in strain-dominated flows.

5:06PM G23.00007 Sedimentation of polygonal tiles. NARAYANAN MENON, ALYSSA CONWAY, Department of Physics, U. of Massachusetts Amherst, RAHUL CHAJSWA, TIFIR International Center for Theoretical Sciences, RINTARO KIRIKAWA, Department of Physics, U. of Massachusetts Amherst, SRIRAM RAMASWAMY, Department of Physics, Indian Institute of Science — We study the stokesian sedimentation of planar shapes by experiments in which polygonal tiles are placed in a vertical plane and sedimented at low Reynolds numbers number in a quasi-two-dimensional container. We focus on the effect of shape-polarity by studying isosceles triangles of varying apex angles. Unlike nonpolar shapes, a triangle rotates as it sediments due to coupling between the orientational and translational degrees of freedom, and asymptotically approaches a stable orientation [Jayaweera, Mason, J. Fluid Mech. 22 (1965)]. For small apex angles the triangle is stable with apex pointing down along the gravity direction. As the apex angle is increased we find a transition at π/3 for which all orientations of the triangle are stable and for apex angles greater than π/3, the triangle is stable with apex pointing up. We understand the experimental results with a model of three stokeslets fixed to the vertices of a triangle. The transition described above, and the coupling of orientation to horizontal drift are captured by this model. We also test generalizations of this discrete-stokeslet model to other regular and irregular polygons and to concave shapes.

5:19PM G23.00008 Motion of an approximate sphere in a Brinkman medium. D. PALANIAPPAN, Department of Mathematics & Statistics, Texas A&M University, Corpus Christi, O. S. PAK, Department of Mechanical Engineering, Santa Clara University — The motion of an approximate sphere through a porous medium modeled using the Brinkman equation is investigated. Analytic solutions for the velocity and pressure fields due to the translation of a perturbed sphere in a Brinkman medium are found using the Stokes stream function approach. Explicit expression for the stream function is obtained to the first and second order in the small parameter characterizing the deformation. The cases of prolate and oblate spheroids, which depart only slightly from the spherical shape form, are considered as particular examples and the hydrodynamic force on these non-spherical bodies are evaluated. Beyond the first order of deformation, it is found that the hydrodynamic drag on a non-spherical body depends on the permeability coefficient in manners different from the case of a perfect sphere. These differences suggest the complex interactions between non-sphericity and permeability. Several special cases are deduced from our exact solutions. The results may be applied to investigate the effects of particle geometry in transport and locomotion in porous media.
pressible gas-liquid flows, FABIAN DENNER, FABIEN EVRARD, BEREND VAN WACHEM, Otto-von-Guericke University Magdeburg — Simulating compressible gas-liquid flows, e.g. air-water flows, presents considerable numerical challenges due to the stiff pressure-density-temperature relationship of the liquid and the sharp difference in compressibility at the fluid interface. We present a fully-coupled pressure-based algorithm for the simulation of interfacial flows in all Mach number regimes, based on a conservative finite-volume discretisation and a VOF-PLIC method to represent the interface, which treats the continuity equation as an equation for pressure and solves the discrete governing equations in a single linear system of equations. In this contribution, we focus especially on the implementation of the discretised governing equations and on different thermodynamic closures based on the Noble-Abel-stiffened-gas model in fully-compressible and polytropic form. Results of representative test-cases, e.g. pressure-driven bubble collapse or the interaction of shocks with bubbles and drops, are presented to scrutinise the presented algorithm and to highlight the differences caused by the considered thermodynamic closure models.

4:14PM G24.00003 Pressure-based algorithm and thermodynamic closure for compressible gas-liquid flows, FABIAN DENNER, FABIEN EVRARD, BEREND VAN WACHEM, Otto-von-Guericke University Magdeburg — Simulating compressible gas-liquid flows, e.g. air-water flows, presents considerable numerical challenges due to the stiff pressure-density-temperature relationship of the liquid and the sharp difference in compressibility at the fluid interface. We present a fully-coupled pressure-based algorithm for the simulation of interfacial flows in all Mach number regimes, based on a conservative finite-volume discretisation and a VOF-PLIC method to represent the interface, which treats the continuity equation as an equation for pressure and solves the discrete governing equations in a single linear system of equations. In this contribution, we focus especially on the implementation of the discretised governing equations and on different thermodynamic closures based on the Noble-Abel-stiffened-gas model in fully-compressible and polytropic form. Results of representative test-cases, e.g. pressure-driven bubble collapse or the interaction of shocks with bubbles and drops, are presented to scrutinise the presented algorithm and to highlight the differences caused by the considered thermodynamic closure models.

4:27PM G24.00004 Simulating Multi-Species Compressible Reactive Flow at Low-Mach Number with a High-Order Fully-Implicit All-Speed Flow Solver, ROBERT NOURGALIEV, MATT MCCLELLAND, Lawrence Livermore National Laboratory, LAWRENCE LIVERMORE NATIONAL LABORATORY COLLABORATION — We present a high-order, fully-implicit all-speed fluid dynamics solver for simulating multi-species compressible reactive flow at very low-Mach numbers. The work is motivated by the development of high-explosive cookoff simulations, which requires modeling multi-species/multi-phase reactive melt convection physics over long time-scales. The governing equations are discretized in space up to 5th-order accuracy with a reconstructed Discontinuous Galerkin method and integrated in time with L-stable fully implicit time discretization schemes. The resulting set of non-linear equations is converged using a robust physics-block based preconditioned Newton-Krylov solver. We demonstrate that our fully-implicit flow solver is able to robustly converge multi-species compressible flow calculations with Mach numbers less than 10^-5. Furthermore, our fully-implicit framework allows for large time steps relative to fast chemical kinetic timescales, which result in highly stiff linear systems.

4:40PM G24.00005 A Dual Scale Model for Reconstructing Sub-Filter Shear Driven Instabilities, AUSTIN GOODRICH, MARCUS HERRMANN, Arizona State University — A method to compute sub-filter shear-induced velocity on a liquid-gas interface for use in a dual-scale LES-DNS model is presented. The method computes velocity perturbation growth rates by constructing a linear eigenvalue problem based on the well known Orr-Sommerfeld equation using a velocity profile approximated with an error function scaled by the far-field velocities and a prescribed boundary layer thickness. The Orr-Sommerfeld equation, along with appropriate boundary and interface conditions, is then solved numerically with a Chebyshev collocation method as outlined by Schmid and Henningson (2001). The eigenfunctions of the Orr-Sommerfeld equations are expanded into Chebyshev polynomials and evaluated at their Gauss-Lobatto points for spectral accuracy, resulting in an algebraic eigenvalue that can be solved using a standard linear algebra package. With the unstable growth rates computed, the streamfunction definitions are used to compute the normal velocities at the liquid-gas interface. The Chebyshev method is tested under a variety of conditions, and results are presented and compared against prior literature.

4:53PM G24.00006 A stabilized coupled level set and volume of fluid method for incompressible two-phase flow at high Reynolds number and high density ratio, HAN LIU, Department of Mechanical Engineering & St. Anthony Falls Laboratory University of Minnesota, QIANG GAO, Department of Mechanical Engineering University of Minnesota, LIAN SHEN, Department of Mechanical Engineering & St. Anthony Falls Laboratory University of Minnesota — When coupled level set and volume of fluid (CLSVOF) method is used coupling with non-conservative schemes, it can suffer from instability issue when the Reynolds number or the density ratio is high. We present an improved CLSVOF method that is able to simulate two-phase flows at very high Reynolds numbers and large density ratios on Cartesian grid while having high accuracy for turbulent flow resolution. To reduce the error near the two-phase interface, a consistent treatment of mass and momentum transport in the conservative form of discrete equations is employed to solve the nonlinear inertial terms of the Navier-Stokes equations. To resolve the discontinuous momentum across the two-phase interface without oscillation while keeping the accuracy of the numerical solution, a WENO scheme is used for the reconstruction of both velocity and density. The accuracy and robustness of this method are validated by benchmark tests. Quantitative comparisons have been made to show the capability of the method handling realistic two-phase flow problems at high Reynolds numbers and high density ratios.
5:06PM G24.00007 On the use of traction outlet boundary conditions for turbulent multiphase flows1, CYRIL BOZONNET, Grenoble Alpes University, OLIVIER DESJARDINS, Cornell University, GUILLAUME BALARAC, Grenoble Institute of Technology — Due to the finite nature of numerical simulations, computational domains need to be truncated and artificial boundary conditions need to be introduced to close the system of equations being solved. In the context of turbulent multiphase flows, this artificial boundary may lead to the development of unstable backflow patterns in outflow regions and can be the source of wave reflection. Moreover, if the flow is incompressible, the position of the artificial boundary can durably impact the upstream flow. The stabilized traction-free boundary condition has already been introduced in order to mitigate backflow instabilities. In this talk, we will present the improvements that can be obtained by using a non-zero traction boundary condition. Specifically, error level, effect of domain truncation, and surface wave reflection are analyzed. This novel outlet boundary treatment is presented in the context of pressure projection algorithms and interface capturing methods.

5:19PM G24.00008 A numerical model for liquid-vapor flows with arbitrary heat and mass transfer relaxation times and general equation of state1, MARICA PELANTI, ENSTA Paris, MARCO DE LORENZO, Compressor Controls Corporation, PHILIPPE LAFOREN, EDF — We describe liquid-vapor flows by a single-velocity six-equation two-phase compressible flow model with relaxation source terms accounting for volume, heat, and mass transfer. The system of equations is numerically solved by a classical fractional step algorithm, where we alternate between the solution of the homogeneous hyperbolic portion of the model system via a HLLC-type finite volume scheme, and the solution of a sequence of systems of ordinary differential equations for the relaxation source terms driving the flow toward mechanical, thermal and chemical equilibrium. For an accurate description of the thermodynamical processes involved in transient liquid-vapor flow problems it is often important to be able to simulate both instantaneous and finite-rate relaxation processes. In this work we present new numerical relaxation procedures to integrate interphase transfer terms with two significant properties: the capability to describe heat and mass transfer processes of arbitrary relaxation time, and the applicability to a general equation of state. We show the effectiveness of the proposed computational model by presenting several numerical tests in one and two dimensions, including simulations of depressurization and blowdown experiments.

3:48PM G25.00001 Reducing ice adhesion via in-situ electrolysis, HENRI-LOUIS GIRARD, SRINIVAS SUBRAMANYAN, DAVID KHANG, YANG SHAO-HORN, KRIPA VARANASI, MIT — The formation of ice on solid substrate is a consequence of numerous processes such as loss of shape of airfoils, weight increase of structures, heat transfer through roofs, slipperiness of surfaces, and more. Current de-icing technologies such as resistive heating, mechanical fracturing, or chemical spraying are either energy intensive or environmentally problematic. The use of super-hydrophobic surfaces to mitigate ice adhesion has been explored and shown to lead to significant reductions in the adhesion strength of ice as long as the texture was not penetrated by the ice. Unfortunately, cold surfaces exposed to humid environments are subject to frost formation which fills the defects and reduces the performance of these substrates. Here, we demonstrate the use of water electrolysis as a means to create stress-concentrators within the ice-adhesion interface in situ. This study investigates the capture of bubbles at the ice-solid interface and the effect of these bubbles on the adhesion of ice on the surface.

4:01PM G25.00002 Bubble Breathing during Dissolution in Confined Geometries under Partial Wetting, KE XU, Massachusetts Institute of Technology, AMIR PAHLAVAN, Princeton University, RUBEN JUANES, Massachusetts Institute of Technology — One expects that, during the dissolution of a gas bubble into surrounding liquid, the bubble volume will decrease monotonically as a result of continuous mass loss. This intuitive picture, however, changes in a surprising way when the dissolving bubble is confined in a geometry under partial wetting to the gas and the liquid. We show that the bubble then experiences cycles of volume expansion (“inhaling”) and shrinkage (“exhaling”), until it fully dissolves. This bubble “breathing” is the result of condensation, growth and merging of liquid droplets on the gas-solid surface, and their eventual expulsion from the gas bubble. Theoretical analysis shows that these counter-intuitive dissolution dynamics are driven by a reduction in the system’s free energy. We provide a scaling argument that identifies the transition from this intermittent expansion-shrinkage “breathing” regime and the classical shrinkage-dominated regime. This behavior could play a major role in determining the macroscopic mass-transfer dynamics in partially wetting systems under confinement, such as oxygen transfer in low-temperature fuel cells and enhanced hydrocarbon recovery in porous rocks.

4:40PM G25.00005 Bubble under field: similarities and differences, SEBASTIEN MAWET, STEPHANE DORBOLO, HERVE CAPS, University of Liège, CYPRIEN GAY, FLORENCE ELIAS, University of Paris Diderot — Deformations undergone by a droplet submitted to an electrical force have been recently studied by Beroz et al. They propose a law based on the equilibrium between capillarity and electrical force. On the other hand, Ikala et al. focus on the dynamics of a ferrofluids droplet resting on a superhydrophobic surfaces under a a magnetic field. They observe the division of a droplet in two smaller ones. Both works show the current interest for the manipulation and the deformation of droplet. Here, we propose to compare with bubbles. We propose to characterize the shape of the bubble submitted to a electric and a magnetic field. Both applied fields lead to similar deformations of the bubble. In particular, we characterize the shape variations of the surface of the hemispherical bubble immersed in the uniform electric field of a plan capacitor. We also observe those variations for a ferrofluids hemispherical bubble under a uniform magnetic field.
4:53PM G25.00006 Numerical Simulations of Gas-Liquid Dispersion in Millichannels Through Parallel Contacting Sections, XIAOJIN TANG, THOMAS ABADIE, OMAR MATAR, Imperial College London — The generation of a regular train of bubbles or droplets in microchannels has been a challenge for the past decade for optimising microreactor design and operation. Although many contacting methods (e.g. T-junctions, cross-junctions) have been studied for single channels, the effects of operating conditions for generating well-controlled bubble dispersions with multiple contacting sections still requires further understanding. For industrial applications, millichannels can be more useful than microchannels to avoid blockage and for higher throughput. However, few research results in millichannels could be found in the literature. We study the gas dispersion in a liquid flowing in a rectangular microchannel through three parallel contacting sections. A finite-volume solver with a Volume-Of-Fluid method to capture the interface is used. The effects of geometry and operating conditions on the gas flow through the contacting sections are analysed along with the breakup frequencies. The effects of contacting section geometry on bubble size distributions and velocities under which stable bubble trains can be formed are discussed as a step towards developing an optimal structure of millichannels where uniform and highly dispersed bubble swarms can be achieved.

5:19PM G25.00008 Bubble pinch-off in turbulence: shape oscillations and escaping self-similarity, DANIEL RUTH, WOUTER MOSTERT, STPHANE PERRARD, LUC DEIKE, Princeton University — Though bubble pinch-off is an archetype of a dynamical system evolving towards a singularity, it has always been described in idealized theoretical and experimental conditions. Using experiments, simulations, and analytical modeling, we consider bubble pinch-off in a turbulent flow, representative of natural conditions in the presence of strong and random perturbations. We show that the turbulence sets the initial conditions for pinch-off, but once the pinch-off starts, the turbulent time at the neck scale becomes much slower than the pinching dynamics: the turbulence freezes. We show that the average neck size, d, can be described by d ∼ (t − t₀)⁻α, where t₀ is the pinch-off, or singularity time, and α ≈ 0.5, in close agreement with the axisymmetric theory with zero initial flow. Neck shape oscillations set by the initial conditions are described by a quasi-two-dimensional linear perturbation model, and persistent asymmetries in the neck are related to the complex flow field induced by the deformed bubble shape. In many cases, a three-dimensional kink-like structure forms on part of the neck just before pinch-off, causing d to escape its self-similar decrease.

3:48PM G26.00001 Vorticity Generation in a Single Nanosecond Spark Discharge Due to Shock Curvature, BHAVINI SINGH, LALIT RAJENDRAN, PAVLOS VLACHOS, SALLY BANE, Purdue University — Spark plasma discharges are generated by raising the voltage difference between two electrodes, until breakdown voltage is reached, resulting in ionization of gas in the electrode gap. This rapid release of energy results in the formation of a shock wave as well as a region of hot gas that expands and cools with time. At later times, vortex rings are formed near each electrode that entrain ambient gas into the electrode gap to cool the hot gas kernel. However, the mechanism(s) responsible for the generation of vorticity in the flow field, and the effect of electrical energy deposited in the gap on this vorticity is unclear. We hypothesize that the shock wave formed at the time of the discharge generates the vorticity by means of baroclinic effects due to shock curvature, and this vorticity field then develops into the pair of vortex rings observed at later times. In this work we develop a detailed analytical framework to relate the vorticity generation to the shock curvature and energy deposited in the electrode gap, and test this framework using 700 kHz shadowgraph and 100 kHz pulse-burst Particle Image Velocimetry (PIV) measurements. We extract the shock curvature from the shadowgraph images and compare the predicted vorticity field from the framework with the measured vorticity field from PIV. These measurements along with the framework will help ascertain the role of shock curvature and energy deposited on the vorticity generation.

4:01PM G26.00002 Design of a zero-net-mass-flux actuator based on a DBD jet in a partially enclosed cavity, ANOOD ALKATHEERI, ABDUL RAOUF TAJIK, ABDULLA ALJABERI, VLADIMIR PAREZANOVIC, Khalifa University, UAE — Recently, Lucas et al. [1] have shown that a shallow cavity at the base of a 3D bluff body can significantly stabilize the symmetry breaking mode of its wake. A natural recirculation of the flow near the base opposes the selection of an asymmetric state, which symmetrizes the wake and yields a higher base pressure (reduced drag). Our work investigates the possibility of recreating this effect, using a partially enclosed cavity with a Dielectric Barrier Discharge (DBD) jet inside. When the DBD jet is activated it produces suction and blowing action at the twin slots and can therefore shift the selection of the transition mode. Current work focuses on the optimal design of such a cavity, using 2D URANS-based simulations in conjunction with the electrodynamic force model of a DBD jet [2]. The dynamics of the DBD jet inside a several different cavity shapes are simulated for steady and periodically pulsed actuation, and the velocity profiles are analyzed. The goal is to establish the most important geometric properties of the cavity for a desired balance between suction and blowing action from the two slits using a single DBD jet.

4:14PM G26.00003 On The Physical Mechanism of Turbulent Boundary Layer Drag Reduction Under AC-DBD Plasma Actuation. SAMARESH MIDYA, ALAN DUONG, THOMAS CORKE, FLINT THOMAS, University of Notre Dame — The results of a series of experiments are reported which use near-wall active flow control designed to intervene in the process of streamwise vortex (SWV) generation, which is primarily responsible for turbulence production in wall-bounded flows. The flow control method utilizes an array of flush mounted AC-DBD plasma actuators in a ZPG TBL over the range of Re = 550-1750. The control flow consists of a series of near-wall, span-wise oriented unidirectional wall jets with velocity comparable to the friction velocity and has been shown to produce significant reductions (around 20%) in drag. The control flow is fully characterized using PIV. The span-wise wall jets inhibit the formation of near-wall SWVs and thus reduce the turbulence production. This manifests itself in the reduction of near wall turbulent Reynolds stress producing events. The focus of the reported experiments is to further clarify the mechanism of drag reduction. X-wire measurements utilizing the quadrant splitting technique are performed downstream of the actuator. These are used to characterize & contrast both the duration of & time interval between quadrant 2 & 4 events in the actuated & non-actuated flows. The quadrant contributions to the Reynolds stress are compared for natural & actuated cases. Effort has been made to correlate the observed drag reduction & the change in Reynolds stress profile. The turbulence statistics have also been compared to similar statistics obtained from a ZPG TBL under pulsed-DC plasma actuation where even higher drag reduction was achieved.

4:40PM G26.00005 High-speed Schlieren visualizations of plasma pulsed jet in subsonic and supersonic regimes. NICOLAS BENARD, Université de Poitiers, YANG ZHANG, Florida State University, HAO-HUA ZONG, MARIOS KOTSONIS, Delft University of Technology, LOU CATTAFESTA, Florida State University, ERIC MOREAU, Université de Poitiers — A novel type of pulsed jet using a spark discharge has been developed in recent years at PPRIME Institute. The device combines a cavity continuously fed by an external pressure source and a plasma discharge propagating from a small needle aligned with the jet orifice. The electric circuit uses a pre-ionization wave to trigger the ignition of the spark discharge. This system has been developed for flow control applications where high-frequency forcing and high momentum injection are both required. The cavity is supplied by constant air pressure at 2.4 bar, producing supersonic jet from the 1-mm diameter orifice. Subsonic conditions can also be achieved by adding a neck extension including a sudden expansion from 1 to 2 mm. In the present investigation high-speed schlieren visualizations have been conducted at a repetition rate of 100 kHz for both supersonic and subsonic operating modes. The energy released is 100 mJ/pulse, and the visualizations clearly demonstrate the strong modulation of the flow conditions from the jet orifice to the surrounding flow region. Precursor and secondary shock waves are visualized as well as the structure of the pulsed jet with a vortex ring formed in front of the jet.

4:53PM G26.00006 Ac-DBD vs Ns-DBD Plasma Actuation on a Turbulent Mixing Layer. ASHISH SINGH, JESSE LITTLE, University of Arizona — A parametric study is undertaken to compare ac-DBD (momentum) and ns-DBD (thermal) plasma actuators in a low speed turbulent mixing layer using an identical load. The mean flow response to each actuation technique is matched at the imposed equivalence in local control authority between the two actuators extends to the global flow, both in the mean and fluctuating components. The ns-DBD plasma actuator requires six times more energy to achieve the same control as the ac-DBD in this specific flow. By studying the flow field very near the splitter plate trailing edge, the difference in momentum versus thermal actuation mechanisms is revealed. A velocity deficit is observed for both actuators, but a thermal bump-like mechanism is responsible in the ns-DBD case while a near surface jet redirecting momentum is found in the ac-DBD case.

5:06PM G26.00007 Vortex Development in a Laminar Separation Bubble measured via Tomographic Particle Image Velocimetry. JOHN KURELEK, SERHIY YARUSEVYCH, University of Waterloo, MARIOS KOTSONIS, Delft University of Technology — The development of shear layer vortices in a laminar separation bubble is investigated experimentally using Planar and Tomographic Particle Image Velocimetry. The experiments are carried out in a series of wind tunnel tests, with the bubble formed on a flat plate subjected to an adverse pressure gradient. Sensitivity to spanwise uniform (2D) and small-amplitude spanwise modulated disturbances (3D) is explored, with disturbances produced using surface mounted dielectric barrier discharge plasma actuators. Compared to the natural case, both types of forcing lead to earlier vortex formation that is rendered essentially two-dimensional at roll-up. While the vortex filaments remain largely two-dimensional until breakdown when subjected to the 2D forcing, deformations rapidly develop within the separation bubble at the spanwise wavelength that matches the input wavelength when 3D forcing is applied. The results elucidate the mechanism responsible for the observed rapid vortex formations from the initially weak spanwise component of the input disturbances and the associated impact on the mean bubble characteristics.

1The authors gratefully acknowledge the National Sciences and Engineering Research Council of Canada (NSERC) for funding this work.
In the present study, the aerodynamic forces acting on a hovering hawkmoth which is feeding on an artificial flower are quantified. The high-speed Schlieren photography results, on the other hand, provide us clear guidelines about how to setup the experiment and when/where to expect the starting vortex. The flow field quantification from the conventional PIV provides us reliable vortex strength data while the high-speed Schlieren photography experiments provide us critical spatial information about the three-dimensional structure of the vortex loop. With those two temporal data quantified accurately, the instantaneous aerodynamic forces can be estimated in the end.

 Recently strategies for mosquito population control have been largely relying on the control of mosquito population. The flight dynamics of mosquito are closely related to their mating and courtship behavior, therefore understand the fluid dynamics can play an important role in developing novel strategies for mosquito population control. In this work, for the the first time, we measure the wake flow of a single tethered mosquito using time-resolved tomographic particle image velocimetry system. Mosquitos are tethered inside a transparent box, and fog particles are used to seed the area. Four cameras, synchronized with the illumination of a Nd: YLF laser, are employed to record the flow field at a speed of 700 Hz (frame straddling mode). The 4D flow structure, pressure field, and flow statistics at the wake of the mosquito are reconstructed and reported in this study.

**3:48PM G27.00001 Dragonfly’s Righting Reflex**

Z. JANE WANG, JAMES MELFI JR, Cornell University, ANTHONY LEONARDO, Janelia Research Campus, HHMI — Insects must right themselves in air so as not to fall. Exactly how insects manage to right themselves is a large mystery in neural behavior of animals. The goal of our work is to find clues about their internal actions through careful measurements and analyses of their aerial acrobatics, in the case of a dragonfly. A dragonfly falling upside down can right itself in about 200ms. During this brief episode, not only it has to sense its perilous condition, it also has to respond with proper muscle actions so to modulate the flapping wing motions such to that generate enough aerodynamic torque in order to correct its orientation. Here, we measure the intricate wing modulations of all four wings that a dragonfly employs to make such a maneuver. We further develop a computational model to simulate the righting maneuver so to tease out the key wing asymmetry that leads to a successful recovery. By analyzing the falling trajectory, we calculate the muscle torque dragonfly used to drive the body rotation. We further conjecture a sensory motor pathway during the dragonflys righting reflex in response to the perceived horizon.

**4:01PM G27.00002 Measurement of mosquito wake flow using time-resolved tomographic particle image velocimetry**

ZHONGWANG DOU, PAVLOS VLACHOS, Purdue University — Recent strategies on the control of mosquito-borne diseases have been largely relying on the control of mosquito population. The flight dynamics of mosquito are closely related to their mating and courtship behavior, therefore understand the fluid dynamics can play an important role in developing novel strategies for mosquito population control. In this work, for the the first time, we measure the wake flow of a single tethered mosquito using time-resolved tomographic particle image velocimetry system. Mosquitos are tethered inside a transparent box, and fog particles are used to seed the area. Four cameras, synchronized with the illumination of a Nd: YLF laser, are employed to record the flow field at a speed of 700 Hz (frame straddling mode). The 4D flow structure, pressure field, and flow statistics at the wake of the mosquito are reconstructed and reported in this study.

**4:14PM G27.00003 Measurement of starting vortex strength of a hovering hawkmoth**

YUN LIU, Purdue University Northwest — From the high-speed Schlieren photography, salient flow structures were successfully visualized and captured on a near hovering hawkmoth Manduca. During the down-stroke, a vortex loop was formed with evolving size and strength. Originally, optical flow method was implemented on the Schlieren images and vortical flow field was quantified at certain time instants. However, owing to the three-dimensional nature of the flow structure and its corresponding complexities, the vortical flow field quantification is not always successful and significant uncertainties in starting vortex strength estimation exists. Therefore, in this work, a further step is taken for accurately measuring the strength of starting vortex. To achieve this goal, a time resolved 2D-PIV is conducted on a hovering hawkmoth which is feeding on an artificial flower. The high-speed Schlieren photography results, on the other hand, provide us clear guidelines about how to setup the experiment and when/where to expect the starting vortex. The flow field quantification from the conventional PIV provides us reliable vortex strength data while the high-speed Schlieren photography experiments provide us critical spatial information about the three-dimensional structure of the vortex loop. With those two temporal data quantified accurately, the instantaneous aerodynamic forces can be estimated in the end.

**4:27PM G27.00004 New measure based solely on wake data for hovering performance**

SACHIN SHINDE, Indian Institute of Technology, Kanpur, India, JAYWANT ARAKERI, Indian Institute of Science, Bangalore, India — In case of hovering wherein forward speed (thus work) is zero, the conventional definition of efficiency does not hold; Figure of Merit (FM) is an alternative. However, both efficiency and FM require measurement of input power which is not trivial for hovering birds and insects. We propose a new measure, independent of measuring input power, called ‘jet effectiveness factor (Π)’ defined based on mass, momentum and kinetic energy flux data, essentially requiring only wake velocity field which can be gathered using PIV, MTV. Inverse of Π can be thought as efficiency. We theoretically calculate Π for two-dimensional (2D) rectangular, triangular and Gaussian jets as 1, 1.250 and 1.1548 respectively. Closer the value of Π to 1, more effective would be the jet. From PIV experiments, we calculate Π for 2D reverse Karman jet generated by flexible foil flapping in an otherwise quiescent ambient - situation relevant to hovering, and show that the value of Π is close to that for Gaussian jet for several cases obtained by varying pitching amplitude and frequency. This new measure can be extended to calculate effectiveness of jet generated by MAVs, AUVs and cruising fish, birds, insects where measuring input power is non-trivial.

**4:40PM G27.00005 ABSTRACT WITHDRAWN —**
4:53PM G27.00006 Why are long sequences of steady flight less common at higher speeds of forward flight in Hawkmoth?1. CHENG-YU LI, MICHAEL CORBI, Villanova University, TYSON HEDRICK, University of North Carolina at Chapel Hill — The hawkmoth is able to sustain a steady hover or level flight at lower speeds (0.7 m/s). However, previous wind tunnel experiments suggested that long sequences of steady forward flight were less common at higher flying speeds (>2.0 m/s) despite changes to the flight posture and muscle recruitment. Considering hummingbirds have about the same body size and can easily achieve ~10 m/s forward flight speed, it is unclear why hawkmoths were not observed achieving steady fast flight. In this work, high-speed photogrammetry and 3D surface reconstruction were used to investigate a hawkmoth’s (Manduca sexta) wing kinematics at a forward flight speed of 4 m/s. The associated fluid dynamics and wing aerodynamic performance were then studied using an in-house computational fluid dynamics solver. Quantitative analysis has shown a significant amount of negative lift was generated during upstrokes at this high forward flying speed. Such a negative lift in the upstroke might reduce maximum sustained flight speeds in this species and might represent an adaptation for the hovering feeding mode for which this species is known.

5:06PM G27.00007 Effects of wing-wake interactions on the aerodynamic performances of a hovering rhinoceros beetle.1. SEHYEONG OH, BOOGEON LEE, HYUNMIN PARK, HAECHOEN CHOI, Seoul National University — We investigate the aerodynamic performance of a hovering rhinoceros beetle using numerical simulation and a quasi-steady aerodynamic model. The simulation shows that the wing-wake interactions significantly affect the aerodynamic performance. To examine the wake characteristics behind the wing, we obtain the temporal and spatial distributions of downwash motion from numerical simulation, and show that the downwash motion is non-uniform along the wing spanwise direction, of which magnitude is large immediately after the stroke reversal and small at the end of half stroke. Therefore, we model the wake behind the wing as a non-uniform (in spanwise direction) and sawtooth-type (in time) downwash motion. Also, we combine a quasi-steady aerodynamic model and a momentum theory, together with unsteady and non-uniform downwash motion. The aerodynamic performance predicted by the present aerodynamic model is in good agreement with that of the present numerical simulation.

5:19PM G27.00008 Generation of Sound from Flapping Wings of Mosquitoes1. JUNG HEE SEO, Johns Hopkins University, TYSON HEDRICK, University of North Carolina Chapel Hill, RAJAT MITTAL, Johns Hopkins University — It has long been recognized that mosquitoes use “wing tones” (sound generated by flapping wings) for communication and signaling during mating. Previous experimental studies showed that the wing tone based “communication” between conspecifics is complex, and it conveys important information about fitness and sexual interest. The mechanisms of wing tone generation and the characteristics of its sound field are however not well understood. Mosquitoes (e.g. Culex) that employ wing-tone communication have very unique wing kinematics (high frequency and small stroke amplitude) compared to other insects of similar size and it has been speculated that this facilitated wind-tone communication. In the present study, the generation of wing-tones in a mosquito (Culex) is computationally investigated to explore the speculations. The flow field around a hovering mosquito is simulated by solving the incompressible Navier-Stokes equations using a sharp-interface immersed boundary method, and the aeroacoustic sound is predicted by the Ffowcs Williams and Hawkings equation. The analysis of the simulation data suggests that the kinematics employed by these mosquitoes facilitates efficient generation of wing-tones.

Sunday, November 24, 2019 3:48PM - 5:32PM – Session G28 Bubbly Flow I 610 - Alison Hoxie, University of Minnesota

3:48PM G28.00001 Bubble induced mixing in stratified fluids within a confined domain1. MAATHANGI GANESH, SANG KYU KIM, SADEGH DABIRI, Purdue University — A numerical study of mixing in temperature stratified fluids induced by the motion of monodispersed swarm of bubbles in a thin gap is carried out. The confinement prevents turbulent production and mixing occurs primarily due to transport by the bubble wake. The confinement also causes the bubbles to be flattened between the solid walls, with a gap to diameter ratio of 0.31. Bubbles entrain liquid from the lower, high-density layers and release it in the low density regions, thus causing mixing between the different liquid layers. Simulations are run for void fractions between 3.35% and 13.4%. The strength of stratification is varied by changing the Froude number between 4.5 and 12.74. We observe a zigzag motion of the bubbles attributed to the periodic vortex shedding behind the bubbles, quantified by the bubble velocity autocorrelations. We report the formation of horizontal clusters, the sizes of which are quantified by the cluster size index, and establish a qualitative correlation between the size of the clusters and the rise velocity of the bubbles. The mixing is characterized by three parameters namely, the COX number, diapycnal eddy diffusivity and mixing efficiency. We report an increase in the buoyancy flux across the isopycnals as void fraction increases. The fraction of energy production due to the buoyancy flux increases with the strength of stratification, giving rise to a higher mixing efficiency.

4:01PM G28.00002 Explaining Hydrodynamics- mass transfer interplay in a bubble column column using bubble size distribution1. MANAS MANOHAR MANDALAHALLI, JOHAN NIENHUIS, LUIS MANUEL PORTELA, ROBERT FRANK MUDEDE, Delft University of Technology — Gas-liquid mass transfer in bubbly flows is strongly coupled with its hydrodynamics, an interdependency relevant for many industrial applications. Shrinking bubbles and/or presence of dissolved contaminants influence both transport processes and their interrelation; this makes understanding the interplay quite challenging. In our experimental work, we study the influence of dissolved electrolytes (up to 1M NaCl) on CO2 mass transfer in a homogeneous rectangular bubble column, up to 7% gas fraction. Bubble size distribution, rise velocity and gas fractions are measured by high-speed imaging and digital image processing, while the liquid CO2 concentration by monitoring pH variation. Coalescence inhibition, due to the electrolyte, and dissolving CO2 both lead to a bimodal bubble size distribution with a lower mean bubble diameter, when compared to an ideal N2-water system. Besides an increment in the interfacial area for the mass transfer, the bimodal distribution leads to bubble plume oscillations and recirculation zones in the column; dynamics of the shrinking bubble plume further influences mixing in the column. Our results strongly indicate that the mass transfer can be explained by the influence of the bubble size distribution on the hydrodynamics.

4:14PM G28.00003 Shaping stress fields with spreading bubble streams: applications for biofouling prevention 1, JAMES BIRD 2, MARK MENESSES, C. FREDERIK BRASZ, Boston University, JESSE BELDEN, Naval Undersea Warfare Center — Hard fouling organisms require significant shear stresses to be removed from a ship hull. Recently it has been shown that more frequent grooming requires less shear stress to remove these fouling organisms. By introducing a stream of air bubbles beneath a submerged surface, one can prevent marine biofouling through a continuously applied average shear stress of approximately 0.01 Pa; however, recent studies have shown maximum shear stresses applied by a bubble can be on the order of 200 Pa. Additionally, it has been shown that the period between critical shear stress events rather than an average stress value may be significant in determining the recruitment of settling marine organisms. Considering these recent developments, we investigate the effect of varying aeration flow rate on the antifouling ability of bubble streams. We find that by decreasing the frequency of bubble production the extent of biofouling prevention also decreases. Using a combination of field data, multiphase PIV, and integral plume theory, we find the shape of the areas influenced by the bubble plumes is related to the lateral spreading of bubbles as they rise.

2There has been confusion in the past regarding another James Bird in our community. This is the only talk in which James C. Bird from Boston University is the presenter.

4:27PM G28.00004 Interaction of a vortex ring with single and multiple air bubbles, SUBHAJIT BISWAS, RAGHURAMAN N GOVARDHAN, Indian Institute of Science — Bubbly turbulent flows occur in many places such as in chemical reactors and in geophysical applications, besides interest from the drag reduction perspective using injected bubbles in a (water) boundary layer. In these flows, the bubbles interact with vortical structures in the flow, this being a two-way coupled interaction. Motivated by such complex interactions of bubbles with vortical structures in turbulent flows, we experimentally study an idealization of this, namely, the interaction of a vortex ring (in water) with single and multiple air bubbles. The main parameters in this case are the ring strength, and a ratio of the bubble volume to ring core volume. In these interactions, we are interested in both the vorticity dynamics and the bubble dynamics, and these are measured using time-resolved PIV and high speed shadowgraphy, respectively. We start with the interaction of a single bubble with a single vortex ring, followed by studies with two or many bubbles (bubble swarm), the latter being closer to the case of bubbly flows. The similarities and differences from the vorticity and bubble dynamics perspectives for the different cases will be presented at the conference.

4:40PM G28.00005 Direct numerical simulation on the effect of slip velocity in bubbly plumes 1, HYUNDUK SEO, Pusan National University, SIVARAMAKRISHNAN BALACHANDAR, University of Florida, KYUNG CHUN KIM, Pusan National University — Bubbly plume is one of the examples of multi-phase flow which is not confined by the sidewall. The bubbly plume has been applied to enhance the mixing for aeration or reaction between the gas and liquid phases. Air-water plume has higher slip velocity rather than other combinations of fluids. In this study, two-phase fluids governing equations are solved by DNS using the spectral element method code Nek5000 with Eulerian-Eulerian approach. To investigate the role of slip velocity in forming a plume structure, we calculated higher-order statistics such as turbulence kinetic energy budget. Not only higher-order statistics but also plume parameters in the conventional integral framework were calculated to quantify and characterize the plume structure. From the statistics, higher slip velocity results in a sharp interface between the inner core region and the outer annular region of the plume. Plume core region with high slip velocity is confined as a column of gas-phase which cannot be dispersed from the centerline. In higher slip velocity cases, TKE production by the buoyancy perturbation happened in the smaller region rather than smaller slip velocity case, but enhanced mean shear around inner plume core has a dominant contribution on the production of TKE.

4:53PM G28.00006 Numerical Simulation of Bubbly Flow and Underwater Acoustics under Breaking Waves based on a Coupled Resolved and Subgrid Scale Bubble Method, QIAN GAO, Department of Mechanical Engineering and Saint Anthony Falls Laboratory, University of Minnesota, GRANT DEANE, Marine Physical Laboratory, Scripps Institution of Oceanography, University of California, San Diego, LIAN SHEN, Department of Mechanical Engineering and Saint Anthony Falls Laboratory, University of Minnesota — Bubbles in breaking waves play an important role in many oceanography processes, including the bubble-mediated air-sea gas transfer, production of ambient wave noise, and marine aerosol generation. To study the bubble entrainment and breaking wave acoustics generation processes, we developed a coupled resolved and subgrid scale bubble simulation method. For bubbles greater than the grid size, which are considered resolved bubbles, we use a coupled level set and volume fraction functions. Bubbles smaller than the grid size, which are called subgrid scale bubbles, are treated with a four-way coupled polydisperse bubble model. Bubble-liquid interaction is accounted for by interfacial forces and void fraction. An underwater noise model is implemented for the generation of noise by wave breaking. It was found that our numerical method can capture the bubble size spectrum and wave noise accurately compared with experimental observations.

5:06PM G28.00007 Spray Atomization Using Bubbles Generated by a Two-Phase Counterflow Mixing Layer, ALISON HOXIE, ERIC JOHNSON, VINOD SRINIVASAN, PETER ROHRBACH, SUO YANG, KRISHNA BAVANDLA, HONGLUAN ZHANG, University of Minnesota — In this study, we employ the well-established phenomenon of the onset of global modes and concomitant rapid breakdown of certain shear layer configurations to design an efficient two-fluid mixer. Low-density jets and countercurrent mixing layers exhibit strong global modes and elevated turbulence levels, leading to rapid mixing, which is relatively insensitive to the viscosity-mediated mean shear stresses. By arranging a liquid and an atomizing gas (air) to satisfy the requirements for the onset of global modes, we are able to demonstrate efficient atomization. It is hypothesized that the observed droplet diameter is proportional to the diameter of bubbles that are created in a two-phase mixing layer inside the atomizer, which depends on the wavelength of the unstable global mode. The droplet data are shown to be relatively insensitive to viscosity. To partially test the hypothesis, Direct Numerical Simulations (DNS) are carried out using Eulerian-Eulerian Volume of Fluid (VOF) approach. Gas and liquid are considered as compressible fluids with perfect gas and perfect fluid equations of state, respectively. Schiller Naumann interphase drag model is used to capture the dynamics of gas bubbles in liquid, and surface tension is considered.
patterns. Such characterization has the potential to improve dynamic anti-fouling mechanisms. Through field experiments and laboratory analysis, we examine the interactions between fluid flow structures, interfaces, and biofouling growth. Various researchers have investigated select hydrodynamic effects, a comprehensive picture linking flow features to fouling development is elusive. As a consequence of both biological and environmental conditions, with the latter including a variety of possible fluid mechanic phenomena. While fuel costs, and even small amounts of fouling can interfere with scientific instruments in the field. It is known that biofouling growth is a consequence of both biological and environmental conditions, with the latter including a variety of possible fluid mechanic phenomena. While various researchers have investigated select hydrodynamic effects, a comprehensive picture linking flow features to fouling development is elusive. Through field experiments and laboratory analysis, we examine the interactions between fluid flow structures, interfaces, and biofouling growth patterns. Such characterization has the potential to improve dynamic anti-fouling mechanisms.

5:19PM G28.00008 Effect of Probe Inserts on the Local Void Fraction in a Bubble Column1, ARUSHI TIWARI, THOMAS J. BURTNETT, THEODORE J. HEINDEL, Iowa State University, EXPERIMENTAL MULTIPHASE FLOW LAB TEAM — Bubble columns are found in many process industries where a gas is bubbled through a liquid to promote mixing, separation, and/or reactions. The local void fraction (also referred to as a gas holdup or volumetric gas fraction) is an important parameter used to quantify flow conditions, and is one measure used to validate computational fluid dynamic simulations. The local void fraction is commonly measured with an inserted probe, but the presence of a probe can also modify local flow conditions and local void fraction. This study uses X-ray computed tomography to quantify the effect different probe geometries have on the time-average local void fraction. The results indicate the local void fraction is slightly higher when probes are inserted into the bubble column, but the overall void fraction is unaffected.

Sunday, November 24, 2019 3:48PM - 5:32PM – Session G29 Biological Fluid Dynamics : Animals 611 - Jamey Jacob, Oklahoma State University

3:48PM G29.00001 Examining the effects of hydrodynamic features on biofouling growth and suppression, LENA DUBITSKY, MARK MENESSES, Boston University, JESSE BELDEN, Naval Undersea Warfare Center - Division Newport, JAMES BIRD, Boston University — The growth of biofouling organisms such as algae, barnacles, and mussels on submerged surfaces is a ubiquitous phenomenon and generally undesirable. Heavy biofouling on ships leads to increased drag and subsequent fuel costs, and even small amounts of fouling can interfere with scientific instruments in the field. It is known that biofouling growth is a consequence of both biological and environmental conditions, with the latter including a variety of possible fluid mechanic phenomena. While various researchers have investigated select hydrodynamic effects, a comprehensive picture linking flow features to fouling development is elusive. Through field experiments and laboratory analysis, we examine the interactions between fluid flow structures, interfaces, and biofouling growth patterns. Such characterization has the potential to improve dynamic anti-fouling mechanisms.

4:01PM G29.00002 Chemical Interactions around Pulsing Soft Corals1, MATEA SANTIAGO, University of California, Merced, LAURA MILLER, University of North Carolina at Chapel Hill, SHILPA KHATRI, University of California, Merced — A subset of sessile Octocorals (Family Xenidae) actively and almost constantly pulse their tentacles. Experimental results indicate that the pulsating facilitates the photosynthesis of the symbiotic algae that live on the Octocorals. It is hypothesized that a significant source of the corals energy is the byproduct of the photosynthesis by the symbiotes. We model the photosynthesis of the symbiotic algae as a gas exchange of carbon dioxide to oxygen, where the coral tentacles are modeled as a source and sink of chemical concentrations. Additionally, the fluid-structure interaction of the pulsing corals, modeled using the immersed boundary method, is coupled to these chemical concentrations. We will present numerical simulations with varying parameters which have been used to gain insight to the complex interactions between the pulse driven fluid flow and the surrounding chemical concentrations.

1NSF PHY grant #1505061 and NSF DMS grant #1853608

4:14PM G29.00003 Mixing and pumping functions in a zebrafish larval intestine1, KENJI KIKUCHI, Department of Finemecanics, Graduate School of Engineering, Tohoku University, HYEONGTAK NOH, KEIKO NUMAYAMA-TSURUTA, Graduate School of Biomedical Engineering, Tohoku University, TAKUJI ISHIKAWA, Department of Finemecanics, Graduate School of Engineering, Tohoku University — Transportation phenomena in the gut are extremely important for digestive, metabolism and absorption in nutrient uptake. The function of mixing and pumping in the intestine, which is a relatively larger vessel in the tracts of the body, has been partially understood in the physiological and medical fields, but not been fully clarified in the physical and mechanical aspects. The flow in the intestine has been recently focused on a distribution of gut flora concerning inflammably bowel disease, diabetes, and cancer. Even though quasi-static distribution analysis of the gut flora has been developed using a next-generation sequencer for medical diagnostics, but mechanical reasons for medical and surgical therapies have not been approached due to invisibility in the body. Here, we proposed in vivo real-time intestinal flow measurement in the larval zebrafish intestine, which has justified similar constriction anatomically and genetically, using a fluorescent particle tracking velocimetry for analysis of mixing and pumping functions of the posterior and interior intestines. Pclt number in the intestines led us to our mechanical understanding; the mixing and pumping functions were crossing over after meal in the zebrafish larva.

1JSPS KAKENHI (Grant No. 17H00853 and 19H02059)

4:27PM G29.00004 Pump Function of C. elegans Pharynx in Highly Viscous Environments, YUKI SUZUKI, KENJI KIKUCHI, Department of Finemecanics, Graduate School of Engineering, Tohoku University, KEIKO NUMAYAMA-TSURUTA, Graduate School of Biomedical Engineering, Tohoku University, TAKUJI ISHIKAWA, Department of Finemecanics, Graduate School of Engineering, Tohoku University — A nematode C. elegans is a filter feeder, which lives in various viscous habitats such as soil and rooting fruits. C. elegans draws a suspension of food bacteria and separates them from the solvent water by using the pharyngeal pump. Former studies have proposed the mechanism of the food condensation only in low viscosity environments. Although C. elegans lives mostly in highly viscous habitats, few studies have investigated the food condensation in highly viscous conditions. Hence, it is not clear how C. elegans can eat bacteria to survive in highly viscous environments. In this study, we investigated the effect of viscosity on the survival of worms and the pump function of the pharynx in highly viscous conditions. We found that the survival rate of worms diminished with increase in viscosity. We also found that the pump function weakened due to higher viscosity while the pump power rose with increase in viscosity. This result suggests that the amount of ingested food declined with increase in viscosity since the pharyngeal pump could expand and contract inadequately in high viscosity. Finally, our results indicate that decrease in the survival rate of worms would be related with decline in the amount of food ingested by the pharyngeal pump in high viscosity.

4:40PM G29.00005 Snail feeding at the air-water interface, DAIISUKE TAKAGI, SOYOUIN JOO, ROBERT COWIE, University of Hawaii at Manoa, SUNGYON LEE, University of Minnesota, SUNGHWAN JUNG, Cornell University — Apple snails exhibit an intriguing feeding behavior at the air-water interface: they deform the foot to set up a funnel-like structure with surface waves traveling radially inwards. We report quantitative measurements of the resultant flow generated on and around the snails. Our observations reveal that distant food particles floating on the interface are effectively drawn in and collected at the center of the funnel. We develop a mathematical model based on lubrication theory to explore plausible physical mechanisms driving the entire system. The snails efficient feeding strategy offers a great source of inspiration for engineering devices designed to drive and control particles along any interface.
Additionally, a cross-wind is implemented to model the effect of the head-wind generated by the forward swimming of the dolphin. A two-phase flow model resolves the entrainment of the mucus in the expelled jet. A combined program of in-situ measurements, experimental setups, and computational simulations has been designed. This study comprises the analysis of their mucus contained in their breath. To capture a dolphin’s breath in the wild, an Unmanned Aerial Systems (UAS) can fly “through” the breath when expelled thus the extent of the exhaled breath is required to properly design the UAS platform. This jet is impulsive, unsteady, two-phase, and in cross flow. A mechanical device has been designed and fabricated to simulate this type of jet for use in wind tunnels and ultimately for UAS aircraft trials. Requirements for this simulator were obtained using three separate dolphins under human care of varying age, weight, and gender by taking high-speed videos of the dolphin’s breath in two planes. PIV measurements were calculated from the videos and used to guide the development of the specialized jet simulator. In addition, existing mass flow data from measurements of dolphins show that these breaths vary from 20-140 liters per second in a time duration of 0.26-0.31 seconds. These requirements were used to design the biologically inspired two-phase jet. Flow measurements of the blow-hole jet dynamics are compared with in-situ field data of actual dolphins.

Dolphin Quest

5:06PM G29.00007 Development of a Simulator to Mimic a Dolphin Blowhole Jet Flow Field

CHRIS BARTON, RICHARD GAETA, ALVIN NGO, MITCHELL FORD, ARVIND SANTHANAKRISHNAN, AARON ALEXANDER, JAMEY JACOB, Oklahoma State University — The health of bottlenose dolphins can be monitored by marine biologists through an analysis of their mucus contained in their breath. To capture a dolphin’s breath in the wild, an Unmanned Aerial Systems (UAS) can fly “through” the breath when expelled thus the extent of the exhaled breath is required to properly design the UAS platform. This jet is impulsive, unsteady, two-phase, and in cross flow. A mechanical device has been designed and fabricated to simulate this type of jet for use in wind tunnels and ultimately for UAS aircraft trials. Requirements for this simulator were obtained using three separate dolphins under human care of varying age, weight, and gender by taking high-speed videos of the dolphin’s breath in two planes. PIV measurements were calculated from the videos and used to guide the development of the specialized jet simulator. In addition, existing mass flow data from measurements of dolphins show that these breaths vary from 20-140 liters per second in a time duration of 0.26-0.31 seconds. These requirements were used to design the biologically inspired two-phase jet. Flow measurements of the blow-hole jet dynamics are compared with in-situ field data of actual dolphins.

Dolphin Quest

5:19PM G29.00008 Two-Phase Computational Fluid Dynamics Simulations of Dolphin Blowhole Expulsion Jets

AARON ALEXANDER, RICHARD GAETA, NGO ALVIN, MITCHELL FORD, JASON BRUCK, HALEY OBRIEN, Oklahoma State University — Monitoring the well-being of the wild dolphin population poses a challenge for biologists. While dolphins in human care can be trained to provide biological samples for monitoring, other methods must be utilized to obtain samples from wild dolphins. It is known that the mucus found in the flow generated from dolphins blowholes can be tested for hormones that help understand the current health status of the dolphin. Yet, the emitted jets from dolphin blowholes have not been well characterized. In order to understand these jets so that adequate samples may be obtained by Unmanned Aerial Systems (UAS) without spooking the dolphins, a combined program of in-situ measurements, experimental setups, and computational simulations has been designed. This study comprises the computational simulation leg of the effort and uses high fidelity scans of a dolphin respiratory system to create a computational fluid dynamic (CFD) replication of the jet emitted from the blowhole. A two-phase flow model resolves the entrainment of the mucus in the expelled jet. Additionally, a cross-wind is implemented to model the effect of the head-wind generated by the forward swimming of the dolphin.

3:48PM G30.00001 The Dynamics of Vesicles Driven through Closed Constrictions by Molecular Motors

YOUNGMIN PARK, THOMAS FAI, Brandeis University — Dendritic spines are postsynaptic processes that often appear in excitatory synaptic connections of principle neurons throughout the brain. Normal function depends on regular replenishment of various membrane proteins, which are transported on vesicles that squeeze through the spine constriction. In the present study, we explore the movements of vesicles in a reduced model of vesicle transport. The model predicts vesicle movement given motor transport parameters such as the ratio of competing motor forces and constriction geometry. We find that for moderately equal motor ratios and moderate constrictions, the movement may be bidirectional, and velocities gain or lose stability through sets of saddle-node bifurcations. For sufficiently tight constrictions, stable velocities vanish through a cusp bifurcation, resulting in one globally stable velocity. We explore the effects of noise on this system, and establish preliminary conditions for general force-velocity curves for vesicle trafficking.

4:01PM G30.00002 Cerebrospinal fluid influx is the earliest contributor to brain edema following stroke

JEFFREY TITHOF, University of Rochester, HUMBERTO MESTRE, TING DU, AMANDA SWEENEY, GUOJUN LIU, University of Rochester Medical Center, LOGAN BASHFORD, EDNA TORO, DOUGLAS KELLEY, University of Rochester, MAIKEN NEDERGAARD, University of Rochester Medical Center — Stroke is one of the leading causes of death worldwide, affecting 10 million people annually. The most detrimental complication is cerebral edema, which is the abnormal accumulation of fluid, thought to enter the brain from the blood. However, we demonstrate that rapid influx of cerebrospinal fluid (CSF) is the principal mechanism for brain edema in the first several minutes following stroke. Specifically, we block a large artery in the brain of a living mouse and then image fluorescent CSF tracers (infused prior to the stroke). By performing particle tracking velocimetry and front tracking velocimetry, we quantify CSF influx at both microscopic and brain-wide scales, respectively. Rapid influx of CSF occurs along the glymphatic pathway, which includes perivascular spaces (annular channels surrounding arteries). Our measurements demonstrate that constriction of arteries following stroke increases the effective size of the perivascular spaces and drives influx of CSF. Our results may lead to novel treatment strategies for stroke and suggest that glymphatic edema may be an important contributor to other acute brain pathologies, such as traumatic brain injury.

4:14PM G30.00003 Hydraulic resistance of periarterial spaces in the brain

1. JOHN H. THOMAS, JEFFREY TITHOF, DOUGLAS H. KELLEY, HUMBERTO MESTRE, MAIKEN NEDERGAARD, University of Rochester — Periarterial spaces (PASs) are annular channels around arteries that carry a flow of cerebrospinal fluid (CSF) into the brain, bringing in nutrients and sweeping away metabolic waste. In vivo observations reveal that PASs are not concentric circular annuli, as often assumed, but instead are oblate and eccentric. We model the PAS cross-section as a circle (artery) surrounded by an ellipse (outer wall), and vary the area, oblateness of the ellipse, and eccentricity of the circle relative to the ellipse. This model can match observed shapes of PASs quite well. For each shape, we determine the velocity profile for steady, laminar flow and compute the corresponding hydraulic resistance. The minimum hydraulic resistance (maximum flow rate) for a given cross-sectional area occurs when the ellipse is elongated and intersects the circle, dividing the PAS into two lobes, as is common around pial arteries. If both boundaries are circular, the minimum hydraulic resistance occurs when the eccentricity is large, as is common around penetrating arteries. We show that the actual shapes of PASs are nearly optimal, offering the least hydraulic resistance for their size: this may well represent an evolutionary adaptation that maximizes the clearance of metabolic waste from the brain.

4:27PM G30.00004 Peristaltic Pumping in an Elliptical-Annulus Model of a Perivascular Space

1. J. BRENNEN CARR, JOHN H. THOMAS, JESSICA K. SHANG, Department of Mechanical Engineering, University of Rochester — Cerebrospinal fluid enters the brain parenchyma through a network of perivascular spaces (PVSs). The flow removes metabolic waste and its disruption is associated with stroke and neurodegenerative diseases. Recent in vivo experiments show that the flow is peristaltically pumped by traveling waves along the arterial wall. We simulate this perivascular pumping in three-dimensional models of the PVS using a finite element solver. The PVS is idealized as an annulus with a circular inner wall and an elliptical outer wall; a sine-wave displacement is propagated along the inner wall. We examine the effects of shape and eccentricity of the annulus and the amplitude and wavelength of the wave on velocity profiles and net flow rates. In contrast to the concentric circular annulus, in which the flow is axisymmetric, the velocity fields in an elliptical or eccentric annulus have an azimuthal velocity component. The net flow is in the direction of the propagated wave and is greater in elliptical and eccentric annuli than in a concentric circular annulus with the same cross-sectional area.

4:40PM G30.00005 Strain accumulation visco-elastic ventriculomegaly hypothesis for the onset of idiopathic Normal Pressure Hydrocephalus (iNPH)

1. STEPHANIE SINCOMB, University of California, San Diego, VICTOR HAUGHTON, School of Medicine- University of Wisconsin, Madison, ANTONIO SANCHEZ, ERNESTO CRIADO-HIDALGO, JUAN C LASHHERAS, University of California, San Diego — Idiopathic Normal Pressure Hydrocephalus (iNPH) also known as Chronic Adult Hydrocephalus is a syndrome characterized by ventriculomegaly, an enlargement of the brain ventricles containing cerebrospinal fluid (CSF), in the absence of elevated intracranial pressure (ICP). Symptoms of iNPH include urinary incontinence, disturbed gait, and dementia. It is most prevalent in the elderly population while extremely underdiagnosed. This condition has been subject of considerable studies, but the question remains of why while the ICP remains normal the ventricles continue to dilate despite free communication between the ventricles and the subarachnoid space. Understanding the mechanisms leading to iNPH is fundamental for its early detection and treatment. This is clinically significant as iNPH is the only potentially reversible neurodegenerative disease. Through Magnetic Resonance Elastography (MRE) measurements of the viscoelastic properties of the brain parenchyma and analytical modeling, we investigate the hypothesis that the reduction in the stiffness of the periventricular white matter and/or a decrease in its permeability leads to a gradual accumulation of the CSF in the brain ventricles and its subsequent enlargement.

4:53PM G30.00006 Numerical simulations and experiments of CSF flow in the spinal canal

1. CANDIDO GUTIERREZ-MONTES, Universidad de Jaen, WILFRIED COENEN, JENNA J LAWRENCE, Univ of California - San Diego, CARLOS MARTINEZ-BAZAN, Universidad de Jaen, ANTONIO L SANCHEZ, JUAN C LASHHERAS, Univ of California - San Diego — Besides the oscillatory velocity driven by the cardiac and respiratory cycles, CSF flow in the spinal canal exhibits a slow steady Lagrangian motion comprising steady-streaming and Stokes-drift contributions, described in recent analytical work. Associated subject-specific descriptions of this bulk flow have revealed the existence of closed Lagrangian recirculating vortices in the lumbar, thoracic, and cervical regions. The structure of these vortices and their relevance in connection with intrathecal drug delivery (ITDD) applications are further investigated in the present study by transient numerical simulations employing a dynamic-mesh fluid-structure interaction method to account for the deformation of the dura membrane. The results show excellent agreement with the previous analytical predictions, which are further corroborated by accompanying in-vitro experiments. The description is extended to account for the buoyancy-driven motion emerging in ITDD procedures as a result of the density mismatch between the drug and the CSF.

5:06PM G30.00007 Modeling Filarial Worm Migration in Lymphatic System

1. KI WOLF, J. BRANDON DIXON, ALEXANDER ALEXEEV, Georgia Institute of Technology — Lymphatic filariasis is a prevalent condition in tropical countries and is caused by intrusion of parasitic worms such as W. bancrofti, which co-parasite between humans and mosquitoes. These parasites can leave debilitating lifelong damage to the lymphatic system. The biophysical traits that enable filarial survival within their lymphatic niche is unknown. To address this problem, we develop a fully coupled, three-dimensional fluid-solid computational model of parasite movement inside the lymphatic vessel. The model is employed to probe parasite movement under various lymph flow conditions. Worm and lymphatic valve parameters are varied to examine the parasite interactions with lymphatic valves. We compare our simulations with recent experiments on filarial movement inside the lymphatic system (Kilaraki 2019). Our results provide insights into the mechanisms behind intralymphatic migration of parasitic worms during the onset and persistence of infection in filariasis.

1Financial support from the National Science Foundation (CMMI-1635133) is gratefully acknowledged.
Motion. We calculate the velocity-velocity correlation functions and the effective diffusivity of passive tracers, and reveal their distinction is the appearance of collective motion in self-propelled particles suspended in a fluid observed in recent experiments and simulations: Milling motions with a hollow core are also observed.

\[ \chi \] of the microswimmers, and the fraction of active microswimmers present in the system (\( \chi \)). We then explore the specificities of the system skull-CSF-brain (flow of the CSF in and out of the skull through the spinal cord, confinement of the CSF...). From there, we show that the energy stored in one bubble only depends on (\( \alpha, \tau \)) and build a phase diagram of the damaging capacity of the bubbles on the brain as a function of (\( \alpha, \tau \)), in good agreement with the prediction of the WSTC.

Sunday, November 24, 2019 3:48PM - 5:32PM – Session G31 Biological Fluid Dynamics: Micro-Swimmer General II

3:48PM G31.00001 Clogging of microswimmers at a constriction.¹, PHILIPPE PEYLA, MARVIN BRUN-COSME-BRUNY, University Grenoble Alpes, SALIMA RAFAI, CNRS, ANDRE FOERTSCH, WALTER ZIMMERMANN, Bayreuth University, THEORETICAL PHYSICS TEAM, LIPHY TEAM — We study the clogging of a suspension of photosensitive microswimmers [Chlamydomonas Reinhardtii (CR)] moving to a constriction in a microfluidic device. Swimming cells are fleeing light and accumulate at a gate that is twice larger than a CR. We study the statistics of times between two successive egresses. Our results fall in the general framework of clogging obtained for panicking pedestrians at a gate or granular materials at the exit of a silo: the survival function obeys a power law decrease with times. Our results also show a faster-is-slower effect: when cells are faster, clogging is increased. This phenomenon - very well known in crowd evacuation during a panic - unveils the role of tangential friction between cells at the constriction where unusual densities are reached. Our experimental observations are supported by lattice Boltzmann simulations.

4:01PM G31.00002 Bacterial magneto-convection¹, ALBANE THERY, DAMTP, Cambridge University, LUCAS LE NAGARD, JEAN-CHRISTOPHE ONO-DIT-BIOT, CECILE FRADIN, KARI DALNOKI-VERESS, McMaster University, ERIC LAUGA, DAMTP, Cambridge University — Magnetotactic bacteria are prokaryotic microswimmers that synthetize magnetosomes, which are chains of nano-magnets in their cytoplasm. Under external magnetic fields these cells are subject to magnetic torques and thus passively align along magnetic lines, providing a simple control mechanism. We use microfluidics experiments to show that collective motion arises from an initial uniform distribution of magnetotactic bacteria under confinement when an external magnetic field is applied. Dense suspensions of magnetotactic bacteria of strain AMB1 are driven toward a glass capillary wall by a magnetic field perpendicular to the channel walls. Their initial random spacing on the surface becomes unstable due to attractive hydrodynamic interactions between swimmers. These interactions result in bacterial magneto-convection: bacterial plumes perpendicular to the wall emerge spontaneously and develop into self-sustained convection cells. The plumes grow and merge and their dynamics is studied experimentally by measuring their wavelength and the flow they generate. Using a numerical model based on hydrodynamic singularities, we are able to capture quantitatively the instability observed in the cell suspension and reproduce the flow field as well as the long-time clustering dynamics.

4:14PM G31.00003 Phase transitions in the system of active and passive microswimmers, NAVEEN KUMAR AGRAWAL, PALLAB SINHA MAHAPATRA, Indian Institute of Technology Madras, Chennai (600036), India — We study the steady-state phases and their transition in a system of active and passive microswimmers. The active and passive microswimmers are initially, randomly distributed in a fluidic medium inside a square enclosure. The active microswimmers move by a constant magnitude self-propulsion force. Whereas, the passive microswimmers have no self-propulsion force, and they move by force exerted by the fluid and the other neighboring microswimmers. A microswimmer's interactions with other microswimmers and the fluidic medium govern the direction of the exerted thrust on it. We have used a discrete particle model to solve the governing equations. Here, the hydrodynamic interaction is modeled as Stokes drag. The phase transition depends on the coordination coefficients (identified by a parameter \( \chi \)) of the microswimmers, initial states of the microswimmers, and the fraction of active microswimmers present in the system (\( \rho \)). At low \( \chi \), the microswimmers exhibit a random motion. For the higher \( \chi \) values, the phase transits from random motion to the milling phase, where microswimmers rotate around the core. Milling motions with a hollow core are also observed.

4:27PM G31.00004 Correlations in microswimmer suspensions, VIKTOR SKULTETY, ALEXANDER MOROZOY, University of Edinburgh, UK — Recent years witnessed a significant interest in physical, biological and engineering properties of self-propelled particles, such as bacteria or synthetic microswimmers. The main distinction of this ‘active matter’ from its passive counterpart is the ability to extract energy from the environment and convert it into directed motion. One of the most striking consequences of this distinction is the appearance of collective motion in self-propelled particles suspended in a fluid observed in recent experiments and simulations: at low densities particles move around in an uncorrelated fashion, while at higher densities they organise into jets and vortices comprising many individual swimmers. Here, we present a novel kinetic theory that predicts the existence of strong correlations even below the transition to collective motion. We calculate the velocity-velocity correlation functions and the effective diffusivity of passive tracers, and reveal their non-trivial density dependence. The theory is in quantitative agreement with our recent Lattice-Boltzmann simulations (J. Stenhammar et al., Phys. Rev. Lett. 119, 028005 (2017)) and captures the asymmetry between pusher and puller swimmers below the transition to collective motion.
4:30PM G31.00005 Auto-phoretic nanorods driven up the wall by gravity, QUENTIN BROSSEAU, New York University - Courant Institute, FLORENCIO BALBOA USABIAGA, Flatiron Institute, ENKELEIDA LUSHI, New Jersey Institute of Technology, YANG WU, New York University, LEIF RISTROPH, New York University - Courant Institute, MIKE WARD, New York University, MIKE SHELLEY, JUN ZHANG, New York University - Courant Institute — Gravitaxis is the directed upward motion of microorganisms against gravity, and is observed for a few ciliated organisms like Chlamydomonas, Euglenas or Paramecium. Lacking a dedicated sensor, their gravitactic response relies on bottom-heavyness or shape anisotropy to induce a bias in their swimming direction. Here we study the gravitaxis of heavy self-electrophoretic Janus nanorods that move upwards on a steeply inclined substrate. Comparisons in experiments and simulations between homogeneous and bottom-heavy nanorods reveal two mechanisms contributing to the gravitactic response of the latter: a buoyancy torque and hydrodynamic interactions with the wall. We show that lubrication forces induce an effective fore-aft asymmetry on nanorods that reinforces the orientation bias to move up the steep wall against gravity.

4:50PM G31.00006 Transport and Dynamics of Swimming Microorganisms in Time-Periodic Flows¹, RANJIANGSHANG RAN, BOYANG QIN, BRENDAN BLACKWELL, PAULO ARRATIA, University of Pennsylvania — Microorganisms often need to navigate through complex fluid environments to successfully feed and reproduce. Examples include algae in oceans and lakes, bacteria in gastrointestinal tracts, and during the production of food and vaccines. Here, we experimentally investigate the transport and mixing of swimming E. coli in two-dimensional time-periodic flows using particle tracking velocimetry and dye mixing experiments. Mixing is assessed by computing stretching fields and finite-time Lyapunov exponents (FTLE) from experimentally measured velocity fields. Velocimetry data shows that bacteria lowers the peak velocity and vorticity of the flow. This result is a function of bacteria concentration and flow geometry; that is, flow separatrices hinder mixing compared to passive particles likely due to bacteria trapping. Stretching fields show that bacteria shorten the average wavelength of Lagrangian coherent structures (LCSs). Overall, mixing can increase or decrease by the addition of active particles (i.e. swimming bacteria) but there seems to be a non-trivial dependence on Reynolds number, path length, flow geometry, and bacteria volume fraction.

5:06PM G31.00007 Route to bacterial swarming¹, XIANG CHENG, YI PENG, ZHENGYANG LIU, University of Minnesota — Collective motions of active fluids such as bird flocks, fish schools and bacterial swarms demonstrate the intriguing emergent behaviors of nonequilibrium systems. While moving at low density, active entities in an active fluids move collectively with its neighbors at high density, exhibiting strong orientational order at a scale of order larger than the size of individual entities. Although such a disorder-order nonequilibrium phase transition has been previously studied, the detailed kinetics of this transition has not been systematically explored in experiments. Here, using light-controlled E. coli, whose locomotion can be reversibly controlled by light, we experimentally study the kinetic pathway of the swarming transition in 3D bacterial suspensions. The phase diagram of bacterial swarming as a function of bacterial concentration, the velocity of active swimmers and the number fraction of active swimmers is systematically mapped. Moreover, we identify different kinetic pathways for the swarming transition depending on the control parameters. Our results reveal the route to the emergent bacterial swarming and provide new insights into the nonequilibrium phase transition in active fluids.

5:19PM G31.00008 Hydrodynamic interactions of Chlamydomonas with a solid surface¹, ABEL-JOHN BUCHNER, KOEN MULLER, DANIEL TAM, Technical University of Delft — Motile unicellular organisms swim through complex environments and often interact with solid surfaces. Their swimming is influenced by the proximity to solid substrates, through hydrodynamic and steric interactions. These interactions directly influence the cell population density distribution and the residence time in the vicinity of the surface. It is predicted that cell-cell interactions remain unclear and previous experimental studies have often been limited to two-dimensional flow cells, which confine the trajectories of the swimming cells. Here, we investigate the interaction of free-swimming cells with surfaces in an otherwise unconstrained three-dimensional flow chamber. Our tracking experiments focus on the model “puller” organism Chlamydomonas reinhardtii. Swimming cells are recorded simultaneously by four separate cameras and triangulated in three-dimensions. Kinematic statistics are calculated from approximately 30,000 swimming tracks. Our results provide evidence of the existence of a long-range hydrodynamic interaction, which induces orbiting behaviour in the near-surface region.

Sunday, November 24, 2019 3:48PM - 5:32PM — Session G32 Biological Fluid Dynamics: Plant Biomechanics

3:48PM G32.00001 Leaf-to-leaf spore dispersal of rust induced by rainsplash¹, HYUNG-GON PARK, Virginia Tech, SEUNGHO KIM, Cornell University, HOPE GRUSZEWSKI, DAVID SCHMALE III, Virginia Tech, SUNGHWAN JUNG, Cornell University, JONATHAN BOREYKO, Virginia Tech — Rainsplash is an important dispersal mechanism for plant pathogens, but the underlying fluid dynamics are poorly understood. We studied how spore-laden satellite droplets, ejected from rainsplash on a diseased leaf, can subsequently stick to healthy leaves. This natural process was mimicked by rebounding microscopic droplets from an angled superhydrophobic substrate onto an adjacent wheat leaf that was horizontally oriented. The droplets either skipped along the wheat leaf or became stuck, depending upon the droplet’s inertia, the orientation of the anisotropic leaf structure with respect to the droplet’s path of motion, and whether the leaf was untreated or sprayed with a fungicide. A model successfully demarcated skipping versus sticking behavior by comparing the droplet’s inertia against the surface energy required for dewetting to occur upon impact.

3:48PM G32.00002 Leaf-to-leaf spore dispersal of rust induced by rainsplash
Comparisons with published laboratory experiments suggest that the inclusion of TD improves the prediction of sucrose transport speed. This mechanism of spore dispersal enables Sphagnum to carry its spores beyond the turbulent boundary layer where it grows so that they can be carried indefinitely by wind currents, which would not be possible if the spores were launched ballistically. Here we present a finite element analysis of the explosive spore discharge from Sphagnum capsules using ANSYS Fluent. We model the spore capsule as a pressurized cylinder with a disk shaped cap that is pushed by the fluid surrounding it which is taken to be incompressible. The capsule properties of the fluid during the vortex ring is created and models this case qualitatively different than the slug flow from a piston-driven system without a cap. By matching the trajectories of vortex rings in our models to high speed videos of capsule explosions we can determine the initial pressure of the capsule. Moreover by analyzing the flow of vorticity out of the capsule we can determine how the cap affects the optimality of vortex ring impulse and compare Sphagnum vortex rings to the optimal vortex rings produced by animals.

Wind-Induced Damage Propagation in a Branched Tree Forest.

Hydraulic regulation of air spreading in vascular plants using wetted cellulose membranes1, JOOYOUNG PARK, TAEOK GO, JONGEUN RYU, SANG JOON LEE, Pohang University of Science and Technology, BIOFLUID AND BIOMIMIC RESEARCH CENTER TEAM — Plants transport water through xylem vessels using strong negative pressure. Thus, the transport system becomes vulnerable to cavitation. For stable water transport, xylem structures have been evolved. Xylem vessels are interconnected by pit membranes consisting of cellulose fibers that function as hydraulic valves to regulate two-phase flows. In this study, the hydraulic roles of pit membranes to prevent spreading of air throughout xylem vessels were investigated using a model system consisting of channels embedding cellulose membranes. We hypothesized that pit membranes normally remain to be wetted in xylem vessels. We noticed in particular the hydraulic role of water film on air bubble spreading that has been overlooked previously. We elucidated the correlation of dynamic characteristics of air flow and pressure variations with the membrane thickness. As a result, the air spreading exhibits two types of dynamics: continuous and discrete spreading. In addition, the thickness of pit membranes affects the behaviors of water film captured by cellulose fibers. Thus, it is a crucial criterion for the reversible gating of further spreading of cavitation throughout xylem networks of under drought condition.

Superhydrophilic-superhydrophobic water harvester inspired by the wetting property of cactus stem1, NAMI HA, HYEJEONG KIM, SANG JOON LEE, Pohang University of Science and Technology, BIOFLUID AND BIOMIMIC RESEARCH CENTER TEAM — Cacti can survive in extremely dry environment thanks to their unique water collecting ability. In addition to the spine which is one of the water collection systems, cactus stem actually plays an important role for harvesting and storing the absorbed water. In this study, we investigate the flow interaction with a forest of fractal branched trees to predict the propagation of damage that occurs and investigate the resulting flow field in different storm conditions. Also, a tree breakage model is incorporated into our simulations to study the progressive damage propagation in each tree and in the forest.

Controlling intercellular flow through mechanosensitive plasmodesmata nanoneopores2, KAARE H. JENSEN, JAN KNOBLAUCH, Department of Physics, Technical University of Denmark, KARL OPARKA, Institute of Molecular Plant Sciences, University of Edinburgh, KEUNHWAN PARK, Department of Physics, Technical University of Denmark — In plants, plasmodesmata (PD) are nanopores that serve as channels for molecular cell-to-cell transport. Precise control of PD permeability is essential to regulate nutrient transport; moreover, it is involved in growth, tissue patterning, and defense against pathogens. Callose deposition modulates PD transport but little is known of the rapid events that lead to PD closure in response to tissue damage or osmotic shock. We propose a new mechanism of PD closure as a result of mechanosensing. Pressure forces cause the cell wall, or the dumbbell-shaped ER-desmotubule-complex, to be displaced from the equilibrium position, thus closing the PD aperture. Cell wall elasticity and the filamentous protein tethers that link the plasma membrane to the ER complex play a key role in determining the selectivity of the PD pore. This model of PD control compares favorably with experimental data on the pressure-generated closure of PD.

Taylor Dispersion in Osmotically Driven Laminar Flows1, MAZEN NAKAD, Student, JEAN-CHRISTOPHE DROME, THOMAS P. WITELSKI, GABRIEL KATUL, Professor — Sucrose is among the main products of photosynthesis that are deemed necessary for plant growth and survival. It is produced in the mesophyll cells and translocated under positive pressure to different parts of the plant through a hydraulic network (phloem). Progress in understanding this transport mechanism remains fraught with experimental difficulties thereby prompting interest in theoretical approaches and laboratory studies. The Munch’s pressure flow model is considered one of the most commonly accepted hypotheses for describing the physics of sucrose transport in such systems. It is based on osmosis to build an energy potential difference between the source (leaf) and the sink (root). The flow responding to this energy potential is assumed laminar and described by the Hagen-Poiseulle equation. The work here will revisit such osmotically driven flow in tubes by including the effects of Taylor dispersion (TD) on mass transport. It is demonstrated that the time scale for sucrose transport is reduced when adding TD for low Munch number (defined by the ratio of axial to membrane resistance) whereas its effect will decrease for high Munch number. Comparisons with published laboratory experiments suggest that the inclusion of TD improves the prediction of sucrose transport speed.

Oil-water separation using synthetic trees. VIVERITA UMASHANKAR, Virginia Tech, ARUN KOTA, Colorado State University, JONATHAN BOREYKO, Virginia Tech — In the world’s tallest trees, water evaporating from leaves generates enough suction to lift water over 100 m high. Transpiration can similarly be attained in synthetic trees by coupling nanoporous "leaves" with conduits mimicking xylem capillaries. Here, we demonstrate that by adding filters to the free ends of the xylem conduits, the hydraulic load generated by transpiration can be used for oil-water separation. Our synthetic tree was comprised of a vertical array of glass tubes of millimetric diameter, whose upper ends were embedded within a nanoporous ceramic disk and whose lower ends were attached to pre-wet cellulose acetate membranes supported by stainless-steel meshes. After saturating the synthetic tree with degassed water, its synthetic roots (filters) were submerged in a reservoir containing a hexadecane-in-water emulsion. The separation efficiency of liquid entering into the tree was quantified by density and contact angle measurements of permeate extracted from the glass tubes.

3:48PM G33.00001 Global modes in Taylor–Couette–Poiseuille Flow with a permeable inner cylinder. DENIS MARTINAND, Aix Marseille Univ, CNRS, Centrale Marseille, M2P2, Marseille, France, NILS TILTON, Department of Mechanical Engineering, Colorado School of Mines, Golden CO 80401 — The addition to a Taylor–Couette cell of an axial Poiseuille flow and a radial flow associated with a weakly permeable inner cylinder results, at a given rotation rate of the inner cylinder, in adjacent regions of the flow that are simultaneously stable, convectively unstable, and absolutely unstable, making this system fit for obtaining global modes of centrifugal instability. Critical conditions of the instabilities are obtained using the analytical frameworks of linear and non-linear global modes. Besides, dedicated Direct Numerical Simulations implementing the Darcy’s condition on the permeable cylinder are performed to assess the validity of these analyses. Three different set-ups are considered. Fluid injection, in the first set-up, or extraction, in the second, occur along the full length of the inner cylinder. In the third, fluid flux through the inner cylinder evolves from extraction to injection as cross flow reversal occurs. Though correctly predicting the nature and location of the wave-makers governing the global instability, and their critical conditions, the analyses do not explain, however, that the instabilities observed in the numerical simulations take the form of axial stacks of wave-packets characterized by step-ups and step-downs of the temporal frequency.

This material is based upon research supported by the Thomas Jefferson Fund of the Embassy of France in the United States and the FACE Foundation.

4:01PM G33.00002 Randomized Resolvent Analysis of Turbulent Separated Flow over a NACA0012 Airfoil. JEAN HELDER MARQUES RIBEIRO, CHI-AN YEH, KUNIHIKO TAIRA, University of California, Los Angeles — Singularity decomposition of a large resolvent operator for high-Reynolds number fluid flow is computationally and memory intensive. For this reason, the applications of resolvent analysis has generally been limited to 1D or laminar flow problems. We consider randomized analysis for fast computation of the dominant resolvent modes by passing a tall and skinny random test matrix to sketch the large resolvent operator. The operator is then projected onto the low-dimensional subspace spanned by the sketch. By performing SVD on this reduced resolvent matrix, we achieve significant reduction in computational and memory requirements compared to traditional techniques. We apply this randomized approach for a bi-global resolvent analysis on a turbulent mean flow over a NACA0012 airfoil at chord-based Reynolds number of 23,000. While the full resolvent operator is projected using only 10 out of the 750,000 bases, the leading gain, forcing and response modes are accurately captured. We also provide discussions on incorporating physical insights into the randomized algorithm for further computational alleviation.

4:14PM G33.00003 Global instability mode in a baffled Von Karman flow. NICHOLAS WORTH, JAMES DAWSON, Norwegian University of Science and Technology — A low-frequency spectral peak is identified in velocity spectra measured close to the stagnation point of a baffled turbulent Von Karman swirling flow. This observation is consistent across a range of studied experimental datasets (3DSC Scanning-PIV and 2DSC Stereo-PIV measurements) acquired in two different facilities. An attempt is made to recognise the underlying velocity structure through an application of conditional averaging and Proper Orthogonal Decomposition. The structure that emerges takes form of a spherical region located near the tank’s centre of accelerated, unidirectional flow perpendicular to the axial direction. This structure is then observed to precess around the tank’s axis with the frequency of the spectral peak. The dynamics of the recognised feature is then studied via POD-Galerkin projection of the Navier-Stokes equations. This ultimately allows us to track origins of the structure down to the linear term of the projected equations, which is characterised by a pair of unstable eigenvalues. The structure can be, therefore, classified as a global instability mode. A simple sensitivity analysis shows that the characteristic frequency can be controlled via the mean shear in the radial plane.

4:27PM G33.00004 Flow Visualization and Velocity Spectra in a Low Viscosity Round Jet. VINOD SRINIVASAN, IAN WRIGHT, University of Minnesota — Low-density jets are known to exhibit strong non-linear global modes, whose frequency is dependent on the density ration, boundary layer thickness with a weak dependence on viscosity. The separate roles of viscosity gradients has not been investigated experimentally for free shear flows such as round jets. The present research documents the unstable response of a circular jet issuing into an ambient fluid of higher viscosity. Viscosity ratios (ambient-to-jet) of 1 to 40 and jet Reynolds numbers of 500 to 2000 are studied in density-matched, miscible fluids. The mode of breakdown is visualized using fluorescent dye and hydrogen bubble techniques, while the wavelength of the dominant mode is measured through hot-film anemometry. The spatial and temporal growth of instabilities is reported as dependent on viscosity ratio, Reynolds number, and jet shear layer inlet condition. The breakdown process is marked by the emergence of a sharp peak in the frequency spectrum at a distance of half a jet diameter downstream of the exit plane. This peak persists for about 5 diameters downstream, gradually decreasing in magnitude until indistinguishable from the background. The frequency of the peak depends on the viscosity ratio, for any fixed jet Reynolds number.
4:40PM G33.00005 Global mode induced by a symmetry-breaking in a split cylindrical cavity. JESUS O. RODRIGUEZ-GARCIA, Universidad de Navarra, SOLEDAD LE CLAINCHE, Universidad Politécnica de Madrid, JAVIER BURGUETE, Universidad de Navarra — We study experimentally the flow inside a closed cylinder split in two halves at the equator. When these two parts rotate in exact corotation regime the internal flow is essentially in solid-body rotation at the angular velocity of both sides. When a slight difference between the rotation frequencies is established a secondary flow is created due to the differential rotation between halves and restricted to the boundary layer. The behavior of this boundary layer is compared with theoretical and numerical results finding the "sandwich" structure of a Stewartson boundary layer. Time-dependent structures are observed near the cylindrical wall. Their behavior for different values of the Reynolds and the Rossby numbers are presented. A global recirculation mode is also found due to a symmetry-breaking induced between sides that appears because of a slight misalignment of the experimental setup, whose characteristics are compatible with the behavior of a processing cylinder. A HODMD analysis is performed finding relevant frequencies inside the flow that allow us to reconstruct the global mode.

1 FIS2017-83401-P

4:53PM G33.00006 Localized eigenmodes in a moving frame of reference representing convective instability. KOEN GROOT, Texas A&M University, SEBASTIEN NIESSEN, University of Liege — When representing convective instability mechanisms with the streamwise BiGlobal stability approach, results suffer from a sensitivity to the streamwise domain truncation length and boundary conditions. The presently proposed methodology resolves this sensitivity by considering a moving frame of reference. In that frame, the spectrum features discrete eigenvalues whose corresponding eigenfunctions decay exponentially in both the up- and downstream directions. Therefore, the truncation boundaries can be placed far enough that both variations in the domain length and artificial boundary conditions have no impact. The discrete nature of the spectrum enables the use of (non-)local stability methods to perform an independent approximation of the BiGlobal eigenvalues via global mode theory. We demonstrate that retrieving set-up-independent solutions in the stationary frame of reference is likely impossible for the flow case considered.

1 FNRS-FIRA fellowship for Sebastien Niessen

5:06PM G33.00007 Global Analysis of the Convective Instabilities in Laminar Shock-Wave/Boundary-Layer Interactions. SEBASTIEN NIESSEN, University of Liege, KOEN GROOT, Texas A&M University, STEFAN HICKEL, Technische Universiteit Delft, VINCENT TERRAPON, University of Liege — The interaction between a laminar boundary layer and an oblique shock wave is investigated through BiGlobal stability analysis. Previous studies have revealed the presence of a stationary mode (J.-Ph. Boin et al., TCFD 20(3), 2006, and J.-Ch. Robinet, JFM 579, 2007) and a convective instability mechanism (F. Guio et al., JFM 789, 2016). In the latter analyses, non-localized eigenmodes are obtained that are artificially affected by the finite size of the chosen computational domain. In the present work, we obtain localized wave packets, that are independent of domain size and truncation boundary conditions, by applying the stability analysis in a moving frame of reference. The long-time behavior is subsequently determined by time integration, which results in the propagation of the localized wave packets in the flow. Finally, we highlight the mechanisms constituting the convective instabilities through a Reynolds-Orr energy budget analysis. To obtain the unstable basic state solution to the compressible Navier-Stokes equations, we have coupled Direct Numerical Simulations to the selective frequency damping method.

5:19PM G33.00008 Linear Stability of Flow through a Compressor Stage. MIGUEL FOSAS DE PANDO, Department of Mechanical Engineering and Industrial Design, University of Cadiz, PETER J. SCHMID, Department of Mathematics, Imperial College London — Fluid systems of industrial interest often consist of a periodic assembly of identical subunits. For instance, a compressor stage in a jet engine is built by arranging a number of airfoil blades in annular rows, one rotating and one stationary. A typical analysis of these systems attempts to describe the flow dynamics by isolating a single subunit, i.e. a blade passage, and imposing periodic boundary conditions. Although this approach leads to problems that are easier to solve, it cannot account for global large-scale synchronization effects across multiple subunits. In this contribution, we first present a computational framework for the analysis of modal and non-modal stability of the full system, i.e. considering the contribution of each subunit to the global dynamics. This technique relies on the underlying properties of operators that are reminiscent of twisted Toeplitz matrices, which are in turn coupled through a time-dependent sliding interface. This framework will be then used to investigate the dynamics of the response of flow through an idealized compressor stage, consisting of a rotor and a stator, to small amplitude forcing.

Sunday, November 24, 2019 3:48PM - 5:19PM — Session G34 Flow Instability: Kelvin-Helmholtz

3:48PM G34.00001 Velocity Measurements and Phase Tracking in a Shock-Driven Multiphase Instability. VASCO O. DUKE WALKER, JOHN MIDDLEBROOKS, ROY ALLEN, WILLIAM MAXON, ALMUHNA SAHIR, Univ of Missouri Columbia, SAMRA KARABEGOVIC, Rock Bridge H.S. Columbia, JACOB A. MCFARLAND, Univ of Missouri Columbia — An experimental investigation has been performed to study physical phenomena induced by the impulsive acceleration of a heterogeneously seeded multiphase flow-field within a shock tube system. In order to achieve this, a cylindrical interface comprising of nitrogen, seeded with micron-sized acetone droplets, was generated within the shock tube's test section and accelerated by a planar shock wave. The nitrogen gas itself was saturated with acetone vapor tracer and mixed into the interface to prevent premature droplet evaporation. The development of both the dispersed and carrier phases was captured through a series of Planar Laser Mie Scattering (PLMS) and Planar Laser Induced Fluorescence (PLIF) images, respectively. In addition, lag effects between the phases were visualized and quantified. The results were compared to simulations for validation. This experimental investigation has a multitude of applications in a variety of scientific and engineering systems, with a particular relevance to systems that involve high-speed or shock-induced multiphase combustion.
4:01PM G34.00002 Liquid film dryout in vertical two-phase annular flow in a rectangular channel, ROMAN MORSE, University of Wisconsin - Madison, TIAGO MOREIRA, University of Sao Paolo / University of Wisconsin - Madison, KRISTOFER DRESSLER, University of Wisconsin - Madison, GHERHARDT RIBATSKI, University of Sao Paolo. LOUISE MCCARROLL, EVAN HURLBURT, Naval Nuclear Laboratory, GREGORY NELLS, ARGANTHAL BERSON, University of Wisconsin - Madison, HEAT TRANSFER RESEARCH GROUP, USP COLLABORATION, MULTIPHASE FLOW VISUALIZATION AND ANALYSIS LABORATORY, UW-MADISON COLLABORATION — The entire liquid-film dryout process in a vertical two-phase annular flow is characterized experimentally, from the initiation of the instability and its development up to the point where the film is completely removed. This system is made of two immiscible liquids in a microfluidic channel with a hydraulic diameter of 18 mm and aspect ratio of 1/3. The walls of the test section are made of glass coated with Fluorine-doped Tin Oxide (FTO). Heat fluxes up to 30 kW/m² are generated at the inner surface of the window by passing an electrical current through the FTO coating. Instantaneous pressure and temperature in the test section, temperature on the outer wall of the test section, and high-speed videos were recorded simultaneously during the dryout event. In addition, the state (wet or dry) of the heated surface was measured using thermoreflectance as a function of time. During the inception of dryout, dry patches on the heated surface may re-wet intermittently. The ability of the surface to rewet near dryout is studied under steady state and pulsatile conditions.

4:14PM G34.00003 Backflow at liquid-gas interface driven by Marangoni effects, HONGYUAN LI, PENCYOU LV, HUILING DUAN, Peking University — Liquid-gas interface on submerged structured surfaces is ubiquitous in nature and has various practical applications. These interfaces, however, are subject to non-uniform surface tension induced by surfactant concentration gradient. Careful PIV experiments with surfactant-laden fluorescent particle solutions show that even trace surfactants have significantly decreased on slip velocity than numerical predictions for surfactant-free flow, and even can produce negative slip velocity (i.e., backflow). We present the mechanism of backflow, which is induced by surfactant concentration gradient. Meanwhile, we investigate the characteristics of backflow. This work is expected to be essential for the design of slippery surfaces and microfluidic devices that are unaffected by Marangoni stress, and it can provide guidance for correcting PIV measurements, especially for the case of liquid-gas interface.

4:27PM G34.00004 Interfacial structure of upward gas-liquid annular flow in an inclined pipe, ADAM FERSHTMAN¹, Tel-Aviv University, LULKAS ROBERS, HORST-MICHAEL PRASSER, ETH Zurich, DVORA BARNEA, LEV SHEMEN, Tel-Aviv University. — In this study, the instantaneous circumferential distribution of the liquid film thickness is examined in upward annular flow of various pipe inclinations. The temporal variation of the film thickness was measured simultaneously across the entire pipe circumference using a multi-range conductance sensor covering about 7 cm in the axial direction. The recording of the temporal and spatial distribution of the film thickness allows investigation of characteristic interfacial wave parameters such as mean film thickness, frequency, wave height distribution, wave propagation velocities, wave length, and more. The interfacial waves observed across the pipe periphery vary with pipe inclination angle, liquid flow rate and circumferential position. These waves were categorized as ripples, disturbance waves or rogue waves, based on parameters such as frequency, wave height and exceedance. The distribution and the total mass transported by the shear driven waves is also examined. For a low liquid flow rate, a transition from stratified wavy to annular flow was documented with increase in pipe inclination. This data is crucial for better understanding and modeling of evolution of annular and stratified flow regimes as a function of gas and liquid flow rates and pipe inclination.

4:40PM G34.00005 Liquid-liquid phase separation in sessile drops induced by evaporation, HOSEIN SADAFI, Université Libre de Bruxelles, RAMIN RABBIANI, University of Lige, SAM DEHAECK, Université Libre de Bruxelles, TIPS LABORATORY TEAM, THERMODYNAMICS OF IRREVERSIBLE PHENOMENA TEAM — The interplay between two phase change mechanisms of evaporation and liquid-liquid phase separation (demixing) in binary sessile drops of partially miscible liquids is investigated. To determine the onset of the demixing phenomenon, a simple model is developed, which predicts a considerable temperature reduction in the mixture due to evaporative cooling. Temperature reduction alongside with the change of composition lead to demixing in the mixtures. Five stages of the process are identified and explained. For the cases studied here, once the demixing begins through nucleation, a growing fingering pattern is formed at the contact line. The length of the fingers is a function of the initial concentration of the low volatile component. Moreover, the final area of deposition increases with the initial concentration. Experimental tests were performed using a double telescopentric lens.

5:05PM G34.00008 Turbulent Faraday instabilities at the interface between miscible fluids, LOUIS GOSTIAUX, Univ Lyon, Ecole Centrale de Lyon, INSA Lyon, Université Claude Bernard Lyon I, CNRS, LMFA, ANTOINE BRIARD, CMLA, ENS Cachan, CNRS Université Paris-Saclay, BENOT-JOSEPH GRA, DIF, DAM, CEA Arpajon, France — We studied turbulent mixing between two miscible fluids of different densities occurring when the stable interface between the denser and lighter fluids is periodically accelerated. Vertical oscillations trigger the well known Faraday instability, that degenerates into turbulence in the case of a miscible interface. Very few studies have been dedicated to the thickening and saturation of this turbulent mixing zone, and to the associated mass transfers. We realized a large set of idealized experiments in a large container (72x12x90cm), where a two layer system of fresh and salty water was subject to sinusoidal vertical oscillations. Motion was controlled by an hexapod providing vertical accelerations up to 0.7g. We could predict, for a given initial concentration of the low volatile component. Moreover, the final area of deposition increases with the initial concentration. Experimental tests were performed using a double telescopentric lens.

5:06PM G34.00007 Two-phase flow instability at a channel outlet, PAUL R. KANEELIL, AMIR A. PAHLAVAN, KENALPHA KIPYEGON, Princeton University, KRISTEN LEROY, KELSEY STENGEL, SAMUEL WARNER, ANNA M. GALEA, Lung Biotechnology PBC, HOWARD A. STONE, Princeton University. — Parallel flow of two immiscible liquids in a microfluidic channel has a variety of applications including solvent extraction, membrane fabrication, chemical processing, and biomedical design. Here, we investigate a system where two immiscible liquids with the same viscosity enter a channel via two inlets, come into contact and form an interface as they flow side-by-side, and subsequently exit the channel via two outlets. We observe an instability at the exit junction, where the interface periodically oscillates and leads to droplet shedding. By systematically exploring the influence of geometric features and fluid flow on the instability, we characterize the underlying mechanism of the instability and offer pathways to control and suppress it.

Taylor dispersion in the presence of cross flow and interfacial mass transfer. TIRAS Y. LIN, ERIC S.G. SHAQFEH, Stanford University — Transverse velocity gradients can enhance the effective diffusion coefficient of a scalar in the primary flow direction, a phenomenon known colloquially as Taylor dispersion. In this work, we perform Taylor dispersion analysis on a pressure-driven flow in a channel with a cross flow, using both perturbation theory and Brownian dynamics simulations. Moreover, we illustrate how mass transfer at the wall affects the evolution of the scalar. We elucidate how the effective diffusion coefficients, effective advective velocities, and effective mass-transfer rates depend on the strength of the cross flow and the wall transfer coefficient, and we perform an asymptotic analysis to investigate the limit of strong cross flow. We discuss a few applications where our results may be useful. For example, in the treatment of a cancerous tumor using nanoparticles, interactions with red blood cells drive nanoparticles in the transverse direction toward the porous blood vessel wall, where they can then be transferred through the wall. Additionally, it has recently been shown that applied forces can cause particles to drift laterally in a viscoelastic channel flow. In both of these applications, our results can be used to understand the resulting particle dispersion.

Dispersion control in deformable microchannels. GARAM LEE, ABIGAIL TAYLOR, Brown University, ALAN LUNER, JEREMY MARZUOLA, University of North Carolina at Chapel Hill, DANIEL HARRIS, Brown University — In fully-developed pressure-driven flow, the spreading of a dissolved solute is enhanced in the flow direction due to transverse velocity variations in a phenomenon now commonly referred to as Taylor dispersion. It is well understood that the characteristics of the dispersion are sensitive to the channel’s cross-sectional geometry. Here we demonstrate a method for manipulation of dispersion properties in a single microchannel via controlled deformation of one of the channel’s walls. Using a rapid-prototyped multi-layer microchip, the upper channel wall is deformed by an external pressure source allowing us to characterize the dependence of the dispersion on the deflection of the channel wall and overall channel aspect ratio. Our experimental measurements are compared directly with theoretical predictions.

Identification and decomposition of advective transfer on microtextured surfaces. YANKING WANG, New Mexico State University, TIE WEI, New Mexico Institute of Mining and Technology, WANG’S CFD LAB COLLABORATION, WEI’S CFD LAB COLLABORATION — Through well-designed physical models and high-fidelity numerical simulations, the physics of advective heat and mass transfer on a solid surface embedded with structured micro pillars is revealed. Two types of advection mechanism are identified, local advection and long-range advection, corresponding to the eddy recirculation in the gaps between streamwise neighboring pillars and the fluid circulation between the regimes above and below pillar tips. The flow topologies suggest that the flow of local advection recirculates primarily in xz plane, and the flow of long-range advection recirculates in yz plane. This fact allows for the decomposition of the two mechanisms by averaging the flow quantities in the streamwise and spanwise coordinates. The enhancement of heat and mass transfer by local and long-range advection is examined for typical geometries, and the transition of the primary transfer method between the two mechanisms due to geometrical change is analyzed in detail. The dependence of local and long-range advection on streamwise and spanwise distances between micro pillars is identified, and this offers promising potential for the accurate control of heat and mass flux in micro fluids.

A Quantitative Study of the Effect of Flow on the Photopolymerization of Fibers. MALCOLM SLUTZKY, HOWARD STONE, JANINE NUNES, Princeton University — The gelation resulting from the interaction between a continuously flowing photo-crosslinkable fluid and pulsed-UV light can be used to produce uniform flexible microfibers. We study this process of fiber production by investigating the conditions required for gelation and by developing a steady-state flow model of the gelation process, which captures the effects of UV exposure on the spatial concentration of radical species and molecular oxygen in the direction of flow. Using this model, we are able to predict critical conditions for fiber production and verify these predictions with our experimentally-observed results. Additionally, we define three regimes of fiber production (in which no fibers, non-uniform fibers, and uniform fibers are produced), qualitatively characterize relationships between fiber length and rigidity, and, with insight drawn from the mathematical model, develop guidelines for the standardized production of uniform fibers with predictable and controllable length.

Measurement of pressure field in microchannel flow from velocity data obtained from micro-PIV. SHINGO OTA, Graduate school of Mechanical Engineering, Tokyo University of Science, Japan, KEN YAMAMOTO, MASAHIRO MOTOSUKE, Department of Mechanical Engineering, Tokyo University of Science, Japan — Dynamics inside and outside of cells and bubbles/droplets in microchannels, e.g., mechanical characteristics of cells and interfacial behavior in multiphase flows, are complicated and difficult to be reproduced by the numerical simulation. To understand these phenomena, a measurement technique that can obtain precise pressure fields of liquid is required. A pressure-field calculation from velocity fields is one possible scenario to obtain the pressure field in microscopic domain where inserting pressure probes is hardly achieved. The present study investigates a reconstruction of pressure fields from velocity fields obtained by micro-PIV based on the Navier-Stokes equation. Fast Fourier transformation (FFT) is used in the pressure-field calculation. And the pressure fields calculated from micro-PIV are compared with CFD results. By preparing artificial particle images with different image resolution, we investigate effects of the image resolution and errors due to the PIV analysis on the accuracy of the pressure-field calculation. As a result, it is shown that the method can reproduce the pressure fields despite the fact that the velocity data contains error. Moreover, the accuracy of both the velocity and the pressure fields can be improved as the increase of the resolution of the artificial particle images.
4:53PM G35.00006 Gas-assisted Taylor Cone-Jets1, FRANCISCO CRUZ-MAZO, Univ. Sevilla (Spain), MAX O. WIEDORN, Center for Free-Electron Laser Science, DESY (Germany), MIGUEL A. HERRADA, Univ. Sevilla (Spain), GISEL E. PENEA-MURILLO, JURAJ KNOSKA, Center for Free-Electron Laser Science, DESY (Germany), SASA BAJT, Deutsches Elektronen-Synchrotron (Germany), HENRY N. CHAPMAN, Center for Free-Electron Laser Science, DESY (Germany), ALFONSO M. GANAN-CALVO, Univ. Sevilla (Spain) — We introduce a way to produce steady micro/nano-liquid jets via electric fields together with co-flowing gas streams. We study the dripping-jetting transition of this configuration theoretically through a global stability analysis as a function of the governing parameters involved. Indeed, we derive two coupled scaling laws that predict both the minimum jet diameter and its maximum velocity. The theoretical prediction provides a single curve that describes not only the numerical computations but also experimental data from the literature for cone-jets. Additionally, we performed a set of experiments to verify what parameters influence the jet length. Due to the diameters below 1 micrometer and high speeds attainable in excess of 100 m/s, this concept has the potential to be utilized for structural biology analyses with X-ray free-electron lasers at megahertz repetition rates as well as other applications.

5:06PM G35.00007 An Elastic filament in a time-periodic linear shear flow , VIPIN AGRAWAL, DHIRUDABIDITYA MITRA, NORDITA — We numerically study the dynamics of a free elastic filament in a highly viscous linear shear flow in the absence of inertia and brownian motion. We use a bead-spring model with Rotne-Prager viscosity [1]. In time-independent shear flow the filament shows tumbling, C-buckling, and snake-turn, before becoming straight at late times [2,3,4], for different elasto-viscous numbers, Γ – Dimensionless ratio of viscous and elastic stress. In time-periodic flow (Period T), for Γ < Γ1, as expected the filament comes back to its initial position after one period. Surprisingly, for Γ1 < Γ < Γ2, we find two-cycle – the filament comes back to it’s initial shape not after one but two periods. For Γ > Γ2, we observe complex dynamical behaviors. Our results are independent of choice of initial conditions.

5:19PM G35.00008 Flow physics of single-phase laminar flow through diamond microchannel , SANDEEP GOLI, SANDIP KUMAR SAHA, AMIT AGRAWAL, Indian Institute of Technology, Bombay — Diamond microchannel is a varying cross-section microchannel with diverging and converging flow passages. Flow in such devices has significance in the design of micromixers, micropumps and microreactors. Three-dimensional numerical analysis of single-phase laminar liquid flow has been performed to understand the effect of the given configuration on flow parameters such as pressure drop and Poiseuille number. The results show that pressure drop in given configuration is consistent with theoretical predictions, which suggests that existing correlations for uniform microchannels can be applied to the present configuration. Towards this, an appropriate length scale has been identified to make the hydrodynamic flow resistance of the diamond microchannel is same as that of an equivalent uniform microchannel. This is located at 1/7th of the total length of the microchannel from its inlet. This location makes the hydrodynamic resistance of microchannel independent of its geometric and flow parameters. In addition, flow physics has been studied with the help of velocity, pressure and shear stress profiles.

3:48PM G36.00001 Time Periodic Electroosmotic Flow in Cylindrical Microchannel with Heterogeneous Surface Charge , AMINUL KHAN, PRASHANTA DUTTA, Washington State University — Mixing of species is very slow in microfluidic due to creeping flow. Time periodic electroosmotic flow (EOF) has been used for faster mixing in microdevice by rapid stretching and folding of fluid streams. Furthermore, surface inhomogeneities are also explored to expedite the mixing process. Although several analytical models exist for each individual case, there is no analytical solution for time-periodic EOF in a heterogeneously charged microchannel. In this work, a general analytical model has been developed for time-periodic EOF through cylindrical microchannel by solving Navier-Stokes equation with slip velocity conditions at the channel wall. Results show that the axial variation of surface charge yields diverse flow patterns containing counter-rotating vortices. The extent and strength of vortices are characterized by channel size, charge distribution and the period of electric field. As the electric field frequency or channel diameter increases, vortices are shifted towards the channel surface and the perturbed flow region confined near the channel wall. Also, the number of vorticities depends on the periodicity of the surface charge. Our analytical model can be used for effective micromixer design by manipulating the surface charge pattern.

4:01PM G36.00002 Particle trapping in merging flow junctions by fluid-solute-colloid-boundary interactions1, SANGWOO SHIN, University of Hawaii at Manoa, JESSE AULT, Oak Ridge National Laboratory, AMY SHEN, Ōkinawa Institute of Science and Technology — Merging of different streams in channel junctions represents a common mixing process that occurs in systems ranging from soda fountains and bathtub faucets to chemical plants and microfluidic devices. Here, we report a sudden trapping of colloidal particles in a merging flow junction when the merging streams have a salinity contrast. We show experimentally and numerically that the particle trapping is a consequence of complex interactions between diffusionosmosis, diffusiophoresis, and the freestream flow. A delicate balance of these transport processes results in a stable vortex near the junction that traps the particles in various modes depending on the flow conditions. We use 3-D particle visualization and numerical simulations to provide a rigorous understanding of the observed particle trapping phenomenon. The trapping mechanism we identify is unique from the well-known inertial trapping that is enabled by the vortex breakup. As the current particle trapping can occur even at Reynolds number below unity. Our study demonstrates a good example of how nonlinear, coupled fluid-solute-colloid-boundary dynamics can result in peculiar particle behavior in simple flow systems.

4:14PM G36.00003 Non-intuitive behavior in concentrated suspension of ideally polarizable particles in an electric field1. SIAMAK MIREFENDERESKI, JAE SUNG PARK, University of Nebraska Lincoln — Large-scale numerical simulations are used to analyze the dynamics of ideally polarizable particles in concentrated suspensions under the effects of nonlinear electrokinetic phenomena. Particles are assumed to carry no net charge and considered to undergo the combination of dielectrophoresis and induced-charge electrophoresis termed dipolophoresis. The suspension dynamics seems to be hindered up to semi-dilute regimes by the increase in the magnitude of excluded volume interactions. Interestingly, a non-intuitive suspension behavior is observed in concentrated regimes, where the hydrodynamic diffusivity starts to increase with volume fraction and reach a local maximum before decreasing as approaching random close packing. This behavior is rationalized through an examination of the velocity fluctuations, suspension microstructure, and number-density fluctuations. We conclude that the non-intuitive behavior is attributed to a consequence of particle contacts, depending on the dominant mechanism of particle paring. While contacts are expected to occur along the field direction in dilute or semi-dilute regimes, very strong and massive contacts along the direction perpendicular to the applied field arise, promoting the non-intuitive behavior observed in concentrated regimes.

4:27PM G36.00004 Diffusiophoresis in Multivalent Electrolytes1. JESSICA L. WILSON, SUIN SHIM, ANKUR GUPTA, HOWARD A. STONE, Princeton University — Diffusiophoresis is the spontaneous movement of colloidal particles in a concentration gradient of ions. As a small-scale phenomenon that harnesses energy from concentration gradients, diffusiophoresis may prove useful for passively manipulating particles in lab-on-a-chip type applications. Though naturally occurring ions are often multivalent, experimental studies on diffusiophoresis have been mostly limited to monovalent electrolytes. In this work, we investigate the motion of negatively charged polystyrene particles in one-dimensional salt gradients for a variety of multivalent electrolytes. Our results indicate that the valence combination of cation and anions significantly impacts the diffusiophoretic mobility of the particles. In addition, the ion valence also modifies the ambipolar diffusivity, which in turn influences the motion of the particles by changing the timescale at which the concentration gradients evolve. We also develop a 1D model and obtain a good agreement between our experimental and modeling results. Our results are applicable to systems where the chemical concentration gradient is made up of multivalent ions, and motivate future research to manipulate particles by exploiting ion valence.

4:40PM G36.00005 Electrophoresis of Colloids via Asymmetric Rectified Electric Fields. TIMOTHY HUI, JOSHUA LAU, S.M.H. HASHEMI AMREI, GREGORY MILLER, WILLIAM RISTENPART, University of California Davis — Charged particles suspended in a dilute electrolyte solution exhibit complex aggregation and levitation behaviors in response to applied oscillatory fields. In particular, an experimentally observed bifurcation in the particle height over an electrode was recently shown to be qualitatively consistent with a force balance between gravity and an electrophoretic force due to the Asymmetric Rectified Electric Fields (AREF) that occur in electrolytes with unequal mobilities. Here, we elaborate on the dynamics of particle electrophoresis in response to AREFs. Using a combination of optical and confocal fluorescence microscopy, we measure the colloidal particle levitation and aggregation dynamics as a function of the applied field properties and electrolyte composition. We show that the dynamics are broadly consistent with numerical calculations of the AREF driving force, and we discuss the implications for precise control and electrophoretic trapping of particles using oscillatory fields.

4:53PM G36.00006 Nonlinear concentration waves in current monitoring method for measurement of electroosmotic flow. MOHAMMAD BABAR, KAUSHLENDRA DUBEY, SUPREET SINGH BAHGA, Department of Mechanical Engineering, Indian Institute of Technology Delhi — Current monitoring method for measurement of electroosmotic flow (EOF) in a microchannel involves displacement of a binary electrolyte initially filled in the channel by a similar electrolyte but having a different conductivity, under the effect of electric field. A fixed voltage is applied across the channel ends and the temporal change in current is measured. Because a conductivity gradient in a binary electrolyte migrates only due to EOF and not due to electromigration, the time taken by one electrolyte to displace another gives an estimate of EOF. This displacement time is usually independent of whether a high-conductivity electrolyte displaces a low-conductivity electrolyte or vice versa. However, few studies have reported that, for low-conductivity electrolytes, the displacement time depends on whether the displacing electrolyte has higher or lower conductivity than the displaced electrolyte. In this study, we show that this directional dependence of displacement time is a result nonlinear concentration waves, such as shock and rarefaction waves, that form when surface conduction is comparable with bulk conduction. We present analytical expressions for current-time relationship in this regime and validate them with experimental observations.

5:06PM G36.00007 Temperature-gradient induced enhanced load bearing capacity of lubricated systems. SIDDHARTHA MUKHERJEE, Advanced Technology Development Center, Indian Institute of Technology Kharagpur, Kharagpur, India-721302, SUNANDO DASGUPTA, Department of Chemical Engineering, Indian Institute of Technology Kharagpur, Kharagpur, India-721302, SUMAN CHAKRABORTY, Department of Mechanical Engineering, Indian Institute of Technology Kharagpur, Kharagpur, India-721302 — Lubricated systems, which are pretty common in some engineering and biological settings, perform on the basis of their load bearing performances. In recent years, a good volume of research has been directed to strategize the performance enhancement of such devices by coupling interfacial phenomenon like electrokinetics with the substrate deformability. However, the deformation characteristics and subsequent load carrying capacity of such systems in presence of thermal gradient have not been explored. Here, we have unveiled that by exploiting a unique coupling of electrokinetics, externally applied thermal gradient, hydrodynamics and substrate flexibility, one can modulate the load bearing capacity of a planar slider bearing considerably. Our studies reveal that the alteration in the electrical potential distribution upon application of temperature gradient and its influence on the resulting hydrodynamics, coupled with substrate compliance, may give rise to significant enhancement in load capacity. We envisage that this analysis may construct a new window in the context of improved design of lubricated systems where the interplay between thermal, electrokinetic and hydrodynamic aspects can be coupled together.
In laminar pipe flow — a linear-onset regime, a time-periodic non-linear regime with the generation of vortices qualitatively similar to the von Kármán vortex street, and eventually a coherent regime which leads to the mixing of the two fluids. A linear stability analysis reveals the occurrence of five finite wavenumber modes of instabilities. The electro-hydrodynamic instabilities originating upon application of electric field stimulate a pair of shorter-wavelength electric field modes E-I and E-II beyond a critical value of electric Rayleigh number. For higher viscosity difference between the fluids, the relative longer wavelength viscous mode (V-mode) appears. Beyond a critical Schmidt number, a diffusive mode (D-mode) appears, which is qualitatively similar to the interfacial instabilities of the immiscible fluids. The K-mode of instability appears due to contrast in ionic mobility values. The reported phenomenon can be harnessed for microscale mixing, pumping, heat and mass transfer, and reaction engineering.

Sunday, November 24, 2019 3:48PM - 5:32PM –
Session G37 Particle Laden Flows  619 -  Ellen Longmire, University of Minnesota, Twin Cities

4:01PM G37.00002 Effect of turbulent puffs on the Segré-Silberberg effect in particulate pipe flow1, SAGNIK PAUL, ELLEN LONGMIRe, University of Minnesota — Particles in laminar pipe flow tend to accumulate at a certain radius close to the wall. When the flow becomes unstable such that turbulent puffs occur, the puffs can disturb the accumulation of particles. In our current work, we investigate the behavior of polystyrene beads in a neutrally buoyant liquid (μ =1046 kg-m-3) over pipe Reynolds numbers in the laminar and transitional range. In our setup, we observe discrete puffs between Re=2100 and 2600 and study the distribution of particles versus radius. The transition Reynolds number and particle distribution are expected to be dependent on the ratio of the particle diameter (d) to pipe diameter (D), and the particle volume fraction (φ). Particle distributions and motions are observed in planes aligned parallel and perpendicular to the pipe axis using both LED and laser sheet imaging. Images are analyzed to quantify particle position distributions. In laminar flow with D/d=43 and φ =0.005, the maximum concentration of particles occurs at 0.44D. In transitional flow at higher Re, the puffs exhibit strong disturbances near the walls that disrupt the local particle accumulation. The effect and relative importance of these disturbances on particle concentration and velocity will be discussed.

1Supported by NSF(CBET 1605719).

4:14PM G37.00003 Experimental investigation of particle-laden under-expanded jets1, TAEHOON KIM, RUI NI, Johns Hopkins University, JESSE CAPECELATRO, YUAN YAO, GREGORY SHALLCROSS, University of Michigan, MANISH MEHTA, NASA Marshall Space Flight Center, JASON RABINOVITCH, NASA Jet Propulsion Laboratory — We present an experimental investigation of particle dynamics in sonic under-expanded jets. In this study, the mass loading and particle slip velocity are independently controlled by using a particle injector and a particle accelerator, which are integrated together in a hopper-style particle feeding system. An ultra-high-speed Schlieren imaging and a particle tracking system operating at 2-5 million fps were employed to acquire the dynamics of both the gas phase and particle phase. Statistics for both particle-free and particle-laden under-expanded jets in the near field will be discussed. These new results will provide a rich dataset for expanding our knowledge in compressible multiphase flow problems as well as validating models and simulations in this regime.

4:27PM G37.00004 Polydisperse Droplet Size Growth in a Turbulent Air Flow - Effects of Droplet Number Density and Size , SHYAM KUMAR M, PhD Scholar, Department of Aerospace Engineering, Indian Institute of Technology Madras, Chennai 600036, India, S.R CHAKRAVARTHY, MANIKANDAN MATHUR, Professor, Department of Aerospace Engineering, Indian Institute of Technology Madras, Chennai 600036, India — Interaction of polydisperse droplets in a turbulent air flow features prominently in a wide range of phenomena. Here, we present an experimental study on the collective effects of droplet number density (ND) and mean droplet size ($D_{10}$) on the droplet size growth. For each (ND, $D_{10}$), we observe an optimum turbulent intensity and a corresponding maximum droplet size growth rate $R^*$. Interestingly, an increase (decrease) in ND($D_{10}$) doesn’t influence $R^*$ up to some threshold values of ND and $D_{10}$, beyond which a sudden increase in $R^*$ is observed. The observed trend is understood in terms of droplet pair dispersion, as observed from Long Distance Microscopy images. The dispersal of droplet pairs is negligible till the threshold conditions are reached. Surprisingly, a substantial increase in dispersion is observed beyond the threshold values, which potentially increases the collision probability, and hence $R^*$. The opposing effects of ND and $D_{10}$ on collision rates cause a negligible variation of $R^*$ up to the threshold values; however, the effect of ND overrides the effect of $D_{10}$ beyond the threshold values, and hence causes a sudden increase in $R^*$. 

1Supported by NSF(CBET 1605719).
4:40 PM G37.00005 Multi-scale characterization of the effect of gas swirl on two-fluid coaxial atomization. NATHANIEL MACHICOANE, PETER D. HUCK, University of Washington, TIMOTHY B. MORGAN, JULIE K. BOTHELL, Iowa State University, RODRIGO OSUNA-OROZCO, University of Washington, DANYU LI, THEODORE J. HEINDEL, Iowa State University, ALAN L. KASTENGREN, Argonne National Laboratory, ALBERTO ALISEDA, University of Washington — This work aims at developing a better mechanistic understanding of the processes that control droplet formation and transport in coaxial two-fluid atomization. The goal is to experimentally develop spray control strategies and implement feedback control of the spray characteristics. We will present results on the impact of modulation of the swirl ratio (ratio of gas flow rate with tangential momentum to the total gas flow rate) on the physics of the atomization, from the formation of liquid ligaments close to the nozzle, to droplet size and spatiotemporal distributions in the mid-field. This parameter dominates the spray structure when it is above a critical value and its modulation in time has a non-linear effect on the spray dynamics that can be used to shape it towards a desired state (the control goal). Synchrotron X-ray measurements provide detailed information of the spray near-field, while time-resolved optical measurements of the spray structure, as well as the droplet size and velocity, are collected in the mid-field. The response of the spray to the open-loop actuations is captured from these measurements. This is used to develop reduced order model for feedback control and to validate assumptions used for computational, adjoint-based, control strategies.

4:53 PM G37.00006 Dynamics of turbidity currents: Ambient fluid entrainment and basal drag1 JORGE SALINAS, University of Florida, MRUGESH SHRINGARPURE, ExxonMobil Upstream Research Company, MARIANO CANTERO, Instituto Balseiro, National Council of Scientific and Technical Research (CONICET), S. BALACHANDAR, University of Florida — Turbidity currents are sediment laden flows that run along inclined or horizontal surfaces. They are driven by the excess hydrostatic pressure resulted from the density difference between the current carrying sediment and the clear ambient fluid. The amount of particles carried is influenced by the strong coupling between turbulence and suspended sediment. In this work we perform direct numerical simulations (DNS) of spatially evolving, spanwise- homogeneous turbidity currents. We focus our attention on the process of entrainment of clear ambient fluid that happens at the interface between the current and the ambient layer. Moreover, the study of basal drag is performed. Turbidity currents have been studied in the past by means of layer-averaged equation models, which make use of several closure models. Two of these models are the entrainment assumption and the basal drag model. In this work we analyze the dependence of these models with the flow parameters (bulk Richardson and Reynolds numbers) together with the settling velocity of the sediment. We pay attention to the regime where the bulk properties of the flow vary slowly, called normal condition. Furthermore, we analyze the effect of acceleration/deceleration of the flow away from normal condition.

5:06 PM G37.00007 Particle-laden upward jet in a crossflow: particle dispersion and tracking of particle source1 JOOYEON PARK, HYUNGMIN PARK, Seoul National University — We experimentally investigate the particle dispersion due to the vortical interaction in the particle-laden upward jet with a crossflow focusing on a large scale phenomena in multiple planes. We vary the velocity ratio (R) between the jet and crossflow, which is classified into three regimes of no crossflow, 3.0 – 27.42. For each case, the air flow and particle velocities are measured by PIV, and the particle distribution is obtained by planar nephelometry. For lower R, due to stronger counter-rotating vortex pairs (CVPs) in a continuous phase, drag force on particles becomes dominant so that the particles are swept from the jet center near the exit for St << 1, but for St >> 1, the particles tend to travel along the jet center regardless of vortical effects. Interestingly, only for St = 1 (irrespective of R), the particles agglomerate along the jet center before the CVF collapses. Finally, based on these observations, a 3D dispersion model is developed, which is used for the estimation of particle source location and validated with the experimental data.

5:19 PM G37.00008 Physical origins of the dependence of drag force on density ratio through fully-resolved direct numerical simulation of particle-laden to bubbly flow1 VAHID TAVANASHAD, SHANKAR SUBRAMANIAM, Iowa State University — The objective of this study is to understand the dynamics of freely evolving particle suspensions over a wide range of particle to fluid density ratios, from solid particles in a gas (high density ratio) to bubbles in a liquid (low density ratio). The dynamics of particle suspensions are characterized by the average momentum equation, where the dominant contribution to average interphase momentum transfer is the mean drag force. The mean drag is characterized using fully-resolved simulation over a wide range of density ratios in a canonical problem: a statistically homogeneous suspension where a steady mean slip velocity between the phases is established by an imposed mean pressure gradient. We explain the change of mean drag of freely evolving particle suspensions with reference to a fixed bed by considering the emergence of spatial structure in the particle configuration, effect of particle velocity fluctuations, and the mobility of particles. These considerations could be used to develop a physics-based drag law for dispersed multiphase flows. The study of the fluctuations of the drag force on individual particles about the mean drag shows that the force distribution follows a normal distribution with a variance from the mean drag that decreases with decreasing density ratio.

3:48PM G38.00001 Heat transfer and flow structures of Rayleigh-Benard convection in regular porous media1 SHUANG LIU, LINFENG JIANG, Tsinghua University, KAI LEONG CHONG, University of Twente, XIAOJUÉ ZHU, Harvard University, ZHENGANG WANG, University of Science and Technology of China, ROBERTO VERZICCO, University of Rome Tor Vergata, RICHARD STEVENS, DETLEF LOHSE, University of Twente, CHAO SUN, Tsinghua University — We report on a numerical study of porous media Rayleigh-Benard (RB) convection for the Rayleigh number Ra from 105 to 110 at various porosities 6. The porous media is constructed by an array of circular, solid obstacles located on a square lattice. For a given 6 two flow regimes are identified with different heat transport properties and flow structures. In the small-Ra regime the heat transport is reduced compared with the classical RB convection without obstacles and the flow is dominated by coherent thermal plumes, while in the large-Ra regime the heat transport is enhanced and the flow is dominated by fragmented plumes. The Nusselt number follows different scaling behaviors in the two regimes, and the regime crossover occurs when the thermal boundary layer thickness is comparable to the particle separation.

We find good agreement between critical depth ratios predicted from our theory and actual values, especially in the small Darcy number limit.

4:40PM G38.00005 Experimental investigation on the scaling of convective dissolution in porous media

Marco De Paoli, Mobin Alipour, Alfredo Soldati, Institute of Fluid Mechanics and Heat Transfer, TU Wien — Porous media convection in Rayleigh-Bénard-type configuration is of paramount importance in many industrial and environmental applications. However, the fundamental behavior of the dissolution flux and its dependence on the system parameters are not yet well understood. Simulations and experiments give opposite indications. In particular, the results of two-dimensional Darcy simulations suggest that the dissolution rate during the convection-dominated regime is constant, whereas Hele-Shaw experiments show that it exhibits a Rayleigh-dependent behavior. With the aid of a novel experimental setup, in which the geometrical properties of the Hele-Shaw cell are varied independently, we obtain accurate measurements of solute fluxes and explain the Rayleigh-dependent character of the dissolution rate observed in previous numerical and experimental studies. Finally, we observe that non-Darcian effects (e.g., mechanical dispersion) may influence the dissolution rate in Hele-Shaw flows and possibly lead to the mismatch between experimental and numerical results.

4:53PM G38.00006 Longitudinal heat conduction effects in a microchannel filled with a porous medium and subjected to a uniform heat flux

Ian Monsivaís, National Autonomous University of Mexico, Jose Lizardi, Autonomous University of Mexico City, Federico Méndez, National Autonomous University of Mexico — The conjugate heat transfer between the walls of a microchannel and a fluid circulating inside is numerically studied. The microchannel is filled with an homogeneous porous medium and subjected to a uniform heat flux on the external walls of the microchannel. The governing equations are written in dimensionless form and basically, we show the existence of two dimensionless parameters that govern the problem: the Darcy number, Da, and the conjugate heat transfer parameter $\alpha_c/\varepsilon^2$. The numerical predictions show that for $\alpha_c/\varepsilon^2 > 1$, the temperature of the fluid at each point of the microchannel is higher than in the case of $\alpha_c/\varepsilon^2 << 1$. These limits are well known as the thermally thin and thermally thick wall limits respectively.

5:06PM G38.00007 Experimental evaluation of thermal transport in partially-porous channel flow

Shilpa Vijay, Mitul Luhar, University of Southern California — While convective heat transfer in channels completely filled with metal foams has been studied extensively, heat transfer in channels that are partially filled with porous foams is less well understood. Previous direct numerical simulations for partially porous channel flow indicate that large vortex structures enhance turbulent heat transfer at the porous medium-unobstructed flow interface. This project aims to experimentally investigate this interfacial thermal transport. The experimental setup involves commercially-available Aluminum foams attached to a heater block and placed in a forced convection arrangement adjacent to an unobstructed channel of equal height. Pressure drop and temperature measurements have been made across the porous section for bulk Reynolds number ranging from 800-3500. Particle Image Velocimetry (PIV) measurements made at a subset of these Reynolds numbers confirm the emergence of interfacial vortex structures in certain conditions. Currently, heat transfer performance in this system is evaluated via estimates of the Nusselt number and friction factor. Ultimately, the PIV dataset will be used to quantify the effect of the interfacial turbulent flow on thermal transport.
Simultaneous measurement of velocity and concentration fields in Hele-Shaw cell. MOBIN ALIPOUR, TU Wien, University of Udine, DR. MARCO DE PAOLI, TU Wien, ALFREDO SOLDATI, TU Wien, University of Udine — Convective dissolution in porous media has a wide range of applications such as sea ice formations, evaporation from soil and geological carbon dioxide storage. While the wealth of computational studies has shed a light on some fundamental features of this flow, experimental techniques currently adopted do not allow an easy, simultaneous and accurate measurement of concentration and velocity fields and we aim precisely at this gap. In this work, we performed experiments in Hele-Shaw geometry and used an optical technique to obtain the solute concentration field. We propose a concentration-based velocity reconstruction (CVR) algorithm, i.e. a new method to reconstruct the velocity field from the solute concentration measurements. In particular, measurements of the concentration gradients are used to reconstruct the velocity field from the momentum transport equation. Effect of gap thickness and non-Darcian behavior of the flow are analyzed by means of both concentration and velocity observations of the fingers. We compare the CVR results with the velocity fields obtained via particle tracking velocimetry (PTV) measurements, giving the guidelines for future experimental works.

Session G39 Geophysical Fluid Dynamics Ocean I 6a - Jim Thomas, Woods Hole

3:48PM G39.00001 Cross-Shore Structure of Alongshore Flow over a Coral Reef Shelf, GENO PAWLAK, ANDRE AMADOR, Mechanical and Aerospace Engineering, UCSD, ISABELLA ARZENO, SARAH GIDDINGS, MARK MERRIFIELD, Scripps Institution of Oceanography, UCSD — Tidally driven alongshore flow over a reef shelf on O‘ahu, Hawai‘i is examined using spatial velocity measurements from an autonomous underwater vehicle (AUV) along with time series observations of the alongshore pressure gradient. Depth-averaged velocities are reconstructed from AUV-based velocity observations as a function of cross-shore distance assuming tidal periodicity. Ensemble averages of the alongshore pressure gradient and velocities versus tidal phase from multiple AUV surveys reveal characteristics akin to an oscillatory boundary layer, with the nearshore flow leading the offshore flow and with a corresponding attenuation in velocity magnitude in shallower regions. Analysis of the depth-averaged alongshore momentum balance indicates that the cross-shore structure and evolution of the tidal boundary layer is strongly modulated by a balance between local acceleration, barotropic pressure gradient, and bottom drag. This primary balance allows estimation of the drag coefficient over depths spanning from 25 to 5 m. Estimates agree with analysis of time series data and compare favorably with drag coefficients estimated from AUV-based roughness mapping. Roughness data suggest that larger scales, at wavelengths comparable to the depth, play a more significant role than smaller meter-scale roughness.

4:01PM G39.00002 Predicting orientation of coastal-zone Langmuir cells influenced by misaligned current, wind and wave forcing, KALYAN SHRESTHA, WILLIAM ANDERSON, UT Dallas — Multi-scale physical processes that involve the interaction between winds, waves, and mean currents regulate turbulence in the upper ocean boundary layer (OBL). Among them, Langmuir turbulence is one such process. In coastal settings, Langmuir turbulence is subjected to additional shear from mean currents. Thus, wind-wave-mean current parameter space and the system response to their disequilibrium becomes an important study for improved parameterizations of OBL processes with wave effects. As such, this investigation considers idealized cases of wind-wave-mean current misalignment and attempts to predict the resultant orientation of coastal Langmuir cells. An a priori predictive model based on mean Lagrangian shear direction is formulated and direct comparisons have been performed successfully with a thorough list of large-eddy simulation results of the Craik-Leibovich equations. The prognostic model as well as the numerical results depict that the resultant cells maintain coherency (although, diminishes with increasing obliquity between the underlying forces) and aligns at an intermediate angle to the range of imposed forces. This was further justified with theoretical developments, which involved analysis of the vorticity transport equation to assess the terms responsible for the sustenance of streamwise vorticity.

4:14PM G39.00003 Study of surface wave effect on the turbulence underneath using wave-phase-resolved simulation, ANQING XUAN, BING-QING DENG, LIAN SHEN, University of Minnesota — The Eulerian orbital motions and the Lagrangian motions of the water surface waves introduce different time scales to the turbulence underneath. In this study, the turbulence dynamics under progressive surface waves are studied using wave-phase-resolved simulations. Compared to the traditional wave-phase-averaged approach of modelling the wave-turbulence interaction, the fast turbulent motions with time scales similar to the waves are directly resolved. Based on the simulation data, we find that the coherent turbulence structures and turbulence statistics are wave-phase dependent. The mechanisms of the wave-phase variation of the turbulence are analyzed in the wave-phase-resolved frame and it is found that the variation is due to the periodic stretching and tilting of the wave orbital straining. The correlations between the wave phase and turbulence statistics, such as the vorticity and Reynolds stresses, are further quantified and their wave-phase-averaged contribution to the wave-turbulence interactions are modelled.

4:27PM G39.00004 Phase-Resolved Ocean Waves Prediction via Machine Learning, FAZLOLHA MOHAGHEGHI, University of California-Los Angeles, MOHAMMAD-REZA ALAM, University of California-Berkeley, JAYTHI MURTHY, University of California-Los Angeles — Phase-resolved prediction of ocean waves is one of the most important outstanding problems in ocean science and engineering. With an accurate prediction of ocean surface height, extreme events such as rogue waves can be braced for, or entirely avoided (e.g. via rerouting of ocean vessels); ocean wave harnessing devices can tune up in real-time to take the most energy out of incoming waves; and the final destination of passive floating particles (e.g. pollutants) can be precisely determined. The problem, however, is very challenging because it uses equations that are not linear; hence even infering wave components that make up a given surface is already a difficult task. Here we show that a Convolutional Recurrent Neural Network (CRNN) has a strong potential to efficiently make real-time prediction of nonlinear non-breaking ocean waves. We use extensive direct simulation of nonlinear ocean waves to train and then test our proposed CRNN-based methodology. Each input node in our CRNN is composed of the discretized surface elevation in a given spatial domain at a specific time. The network takes a time-window of input nodes, and outputs the spatiotemporal prediction of surface waves. Accuracy, reliability and limitations of the proposed methodology are discussed.

4:40PM G39.00005 Machine Learning for Trajectory Prediction in Geophysical Flows1, PHILIP YECKO, Cooper Union, ERIC FORGOSTON, Montclair State University, KEVIN YAO, The Cooper Union — Echo state network based machine learning (ML) is applied to two elementary models of ocean circulation: the well-known double-gyre stream function model with time-variable forcing and a one-layer quasi-geostrophic (QG) basin model. These models are used to generate time-dependent two-dimensional stream function fields, from which flow maps, trajectories and ensembles of trajectories are computed, assuming ideal particles. Varied physical model parameters allow sampling of a wide range of dynamical behaviors corresponding to diverse geophysical flow regimes; the QG PDE model can realize Munk, Stommel or strongly nonlinear time-dependent solutions. We evaluate the effectiveness and fidelity of our machine learning approach in capturing the characteristics of trajectories, both directly and indirectly, via stream function field prediction. We assess the predictive power of ML models against other predictive and descriptive models of QG flows, including finite time Lyapunov exponent, or FTLE, accounting for the role of physical and numerical parameters on our results.

4:53PM G39.00006 Predictability of ROMS-Ocean State Ocean Model using Information Theory

Aakash Sane, Baylor Fox-Kemper, Brown University, David Ullman, Christopher Kincaid, Lewis Rothstein, University of Rhode Island, University of Rhode Island Collaboration, Brown University Collaboration — The Ocean State Ocean Model (OSOM) is an implementation of the Regional Ocean Modeling System (ROMS) covering Rhode Island waterways which includes the Narragansett Bay, Mt. Hope Bay, and nearby regions including the shelf circulation from Long Island to Nantucket. Our focus is on modeling the physical aspects of the Bay in order to build a forecast and prediction system. Perturbed ensemble simulations with altered initial condition parameters (temperature, salinity) are combined with concepts from Information Theory to quantify the predictability of the OSOM forecast system. Predictability provides a theoretical estimate of the potential forecasting capabilities of the model in the form of prediction time scales and enhances readily estimable timescales such as the freshwater flushing timescale. The predictability of the OSOM model is around 10-40 days, varying by perturbation parameters and season.

5:06PM G39.00007 Uncertainty quantification of trajectory clustering in ocean ensemble forecasts

Guilherme Salvador-Vieira, Michael Allshouse, Northeastern University, Irina Rypina, Woods Hole Oceanographic Institution — Identifying coherent structures in unsteady flows helps differentiate flow regions based on material transport. Partitioning flows into regions that minimally mix with their surroundings in the oceans, for instance, can assist search-and-rescue planning by reducing the search domain. One partitioning method is the spectral clustering of trajectories, which maximizes within-cluster similarities while minimizing between-cluster similarities. For ocean applications, however, in addition to the complex dynamics, there are several sources of uncertainty: model initialization and parameters, limited knowledge of the processes, boundary conditions, and forcing terms. Therefore, when applied to ocean forecasting, the clustering method should analyze multiple realizations, identify robust features, and quantify the uncertainty. We present an investigation of the sensitivity of the spectral clustering method to uncertain parametrization and noise through application to simulations of an analytic geostrophic flow model. We then apply this approach to an operational coastal ocean forecast and compare the results with observational drifter data from a field study.

5:19PM G39.00008 Geophysical turbulence dominated by inertia-gravity waves

Jim Thomas, Woods Hole Oceanographic Institution, USA and Dalhousie University, Canada — Recent evidence from both oceanic observations and global-scale ocean model simulations indicate the existence of regions where low-mode internal tidal energy dominates over that of the geostrophic balanced flow. Inspired by these findings, we examine the effect of the first vertical mode inertia-gravity waves on the dynamics of balanced flow using an idealized model obtained by truncating the hydrostatic Boussinesq equations on to the barotropic and the first baroclinic mode. On investigating the wavebalance turbulence phenomenology using freely evolving numerical simulations, we find that the waves continuously transfer energy to the balanced flow in regimes where the balanced-to-wave energy ratio is small, thereby generating small-scale features in the balanced fields. We examine the detailed energy transfer pathways in wave-dominated flows and thereby develop a generalized small Rossby number geophysical turbulence phenomenology, with the two-mode (barotropic and one baroclinic mode) quasi-geostrophic turbulence phenomenology being a subset of it. The present work therefore shows that inertia-gravity waves would form an integral part of the geophysical turbulence phenomenology in regions where balanced flow is weaker than gravity waves.

Sunday, November 24, 2019 3:48PM - 5:32PM —
Session G40 Turbulent Boundary Layers: Curvature and Pressure Gradients I

3:48PM G40.00001 Direct numerical simulation of turbulent flows over curved walls with adverse pressure gradient

Abhiram Aithal, Antonino Ferrante, University of Washington, Seattle — Flow separation over curved walls with adverse pressure gradient (APG) occurs in many aerodynamic applications. However, the physical mechanisms of turbulence over curved bodies with APG are not yet well understood and the wall models employed in Reynolds-averaged Navier-Stokes (RANS) and large-eddy simulations (LES) for such flows need to be improved. In order to provide the necessary statistics for the validation of such models and explain the physical mechanisms of such flows, we have performed direct numerical simulations (DNS) over curved walls with APG. First, we have developed a fully-explicit and direct pressure-correction method to solve the incompressible NS equations in orthogonal curvilinear coordinates called FastRK3. FastRK3 is a three-stage, third-order Runge-Kutta projection-method which requires solving the Poisson equation for pressure only once per time step. Then, we have verified and validated FastRK3 with several test-cases and against available experiments. Last, we have performed a DNS study of the turbulent separated flow over a curved ramp and studied the dynamics of its turbulence kinetic energy.

4:01PM G40.00002 Non-equilibrium three-dimensional boundary layers at moderate Reynolds numbers

Marco G. Giometto, Department of Civil Engineering and Engineering Mechanics, Columbia University, New York 10027, Adryan Lozano-Duran, Center for Turbulence Research, Stanford University, California 94305, George I. Park, Department of Mechanical Engineering and Applied Mechanics, University of Pennsylvania, Pennsylvania 19104, Parviz Moin, Center for Turbulence Research, Stanford University, California 94305 — Non-equilibrium wall turbulence with mean-flow three-dimensionality is ubiquitous in geophysical and engineering flows. Under these conditions, turbulence may experience a counter-intuitive depletion of the turbulent stresses, which has important implications for modeling and control. Current turbulence theories are established mainly for statistically two-dimensional equilibrium flows and cannot predict such a behavior. In the present work, we propose a multi-scale model explaining the response of non-equilibrium wall-bounded turbulence under the imposition of three-dimensional strain. The analysis is performed via direct numerical simulation of turbulent channels at friction Reynolds numbers up to 1000. We show that scaling properties of the Reynolds stress are consistent with a model comprising momentum-carrying eddies with sizes and time scales proportional to their distance to the wall. We further demonstrate that the reduction in Reynolds stress follows a spatially and temporally self-similar evolution caused by the relative horizontal displacement between the core of the momentum-carrying eddies and the flow layer underneath.

This investigation is funded by the Office of Naval Research (ONR), Grant N00014-16-S-BA10
4:14PM G40.00003 Characteristics of the so-called uniform momentum zones and vortical fissures in a turbulent boundary layer downstream of an adverse pressure gradient, ALIREZA EBADI, CHRISTOPHER WHITE, University of New Hampshire — Particle image velocimetry (PIV) data acquired in a turbulent boundary layer downstream of an adverse pressure gradient at high Reynolds number is analyzed to study the characteristics of the so-called uniform momentum zones (UMZs) and vortical fissures (VFs) in the inertial region of the flow (where the viscous forces are subdominant). These characteristics, which include the wall-normal width of the UMZs and VFs, the velocity jump and vorticity across VFs, among others, are compared to those of the zero pressure gradient boundary layer at similar Reynolds number at the same facility.

4:27PM G40.00004 A new correlation for predicting transition Reynolds number of varying turbulence intensity with pressure gradient, WEI-TAO BII, MENG-JUAN XIAO, FAN TANG, ZHEN-SU SHE, Peking Univ. — We report a new finding on the correlation predicting the laminar-turbulent transition of a boundary layer for varying incoming turbulence intensity and pressure gradient. The new correlation displays a simple scaling of the transition Reynolds number on the incoming turbulence intensity, much simpler than previously proposed empirical ones, owing to an introduction of a transition central location parameter by our newly proposed symmetry-based description of the laminar-turbulent transition. Excellent agreement between the theory and the measurement/simulation data is found for the skin friction and wall heat flux distributions throughout the transition, as accurately validated by the T3-series flat-plate transition experiment and computation data. Owing to its simplicity, the transition model using the current correlation may have significant engineering interest. Furthermore, the results demonstrate that one may uncover simple similarity law governing the transition onset for both natural and bypass transitions, once relevant (statistical) multilayer structure of TBL is represented. The discovery of such similarity law does not require detailed analysis of complex instability mechanisms of the transition. Future work would be to quantify more transition effects, e.g., those in hypersonic engineering flows, which has been extremely difficult via the traditional approach.

1 NSF-CAREER 11377008, 11452002

4:40PM G40.00005 The effect of concave surface curvature on supersonic turbulent boundary layers, CHRISTIAN LAGARES, HPCVLab U. of Puerto Rico-Mayaguez, KENNETH JANSEN, U. of Colorado-Boulder, GUILLERMO ARAYA, HPCVLab U. of Puerto Rico-Mayaguez — Unsteady 3D turbulent boundary layers that evolve along the flow direction exhibit a streamwise non-homogeneous condition and pose enormous computational challenges. The reasons are as follows: (i) full spectrum resolution of turbulence, (ii) accurate time-dependent inflow turbulence information, and (iii) compressibility effects. Moreover, accounting for the effects of wall-curved driven pressure gradient adds significant complexity to the problem. In this presentation, we will show recent Direct Numerical Simulation (DNS) with high spatial/temporal resolution of supersonic spatially-developing turbulent boundary layers (SDTBL) subject to strong concave curvature ($\delta_{wall}/R \approx -0.083$, R is the curvature radius) and Mach $= 2.86$, which are of crucial importance in aerospace applications (e.g., unmanned high-speed vehicles and scramjets). The prescribed curved geometry is based on the experimental study by Donovan et al. (J. Fluid Mech., 259, 1-24, 1994). Turbulent inflow conditions are based on extracted data from a previous DNS over a flat plate (precursor). The extensive DNS information will shed important light on the transport phenomena inside turbulent boundary layers subject to strong deceleration or Adverse Pressure Gradient (APG) caused by concave walls.

4:53PM G40.00006 ABSTRACT WITHDRAWN —

5:06PM G40.00007 Adaptive simulations and experiments of the turbulent flow around a NACA 4412 profile at high $Re^1$, FERMIN MALLOR, ALVARO TANARRO, EDA DOGAN, AGASTYA PARikh, NICOLAS OFFERMANS, ADAM PEPLINSKI, RAMIS ORLÜ, RICARDO VINUESA, PHILIPP SCHLATTER, Linne FLOW Centre, KTH Mechanics — Turbulent boundary layers (TLBs) under strong pressure gradients (PG), as appearing on wing surfaces, are still an active research topic. The NACA 4412 has been a benchmark airfoil in the study of PG-TLBS as its surface pressure distribution is only weakly dependent on Reynolds number ($Re$) at moderate angles of attack (AoA). This allows to decouple PG (history) and $Re$ effects affecting the development of the TLB. Using the high-order spectral-element method code Nek5000, large-eddy simulations of a NACA 4412 profile at a $5^\circ$ AoA are carried out. Adaptive Mesh Refinement (AMR) is used to generate a non-conformal mesh highly refined in the boundary layer and wake regions and avoiding the over-refinement of the far-field typical of structured conformal meshes. A larger domain is used while reducing by a factor of three the number of grid points, allowing to increase $Re$, aiming for 1,640,000 used in the experiments of the 1970s and 80s on the same airfoil. Such well-validated simulation data can then be used to understand better the effect of PG and surface curvature, and allow the calibration of turbulence and wall models. Moreover, an experimental campaign is planned in the MTL wind tunnel at KTH, for which wall-liners are designed aiming at reducing blockage effects.

5:19PM G40.00008 Measurements in the near-wake of a turbulent wing-body junction, J. KLEWICKI, J.H. LEE, S. ZIMMERMAN, J. MONTY, University of Melbourne — Turbulent wing-body junction flows arise from the interaction between a turbulent boundary layer and a surface mounted streamlined obstacle, and are frequently encountered in aerodynamic and hydrodynamic applications. This study uses two-dimensional, three component stereo PIV measurements to investigate the statistical and instantaneous properties of a wing-body near-wake at moderate Reynolds number. The measurements were acquired in an open-return boundary layer wind tunnel at the University of Melbourne. The approach zero pressure gradient boundary layer at $f_0 = 10,000$ interacts with a Rood wing composed of a 3.2 elliptical leading edge joined to a NACA 0020 profile, with a chord length $C = 168$mm, maximum thickness $T = 40$mm, and height $H = 80$mm. The freestream velocity was about 20 m/s. Three component velocity measurements were collected at five different streamwise locations ranging from 0.075C to 1C downstream of the trailing edge of the airfoil, whose angle-of-attack was also varied from -15 to +15 degrees in increments of 5 degrees. Results focus on the three dimensional structure of the near-wake flow and the influence of the necklace vortices that form in front of the body and pass through the wake. Variations with angle of attack are described.

4:27PM G41.00004 Effect of detaching force on water retention on a surface1, NEDA OJAGHLOU, DUSAN BRATKO, HOOMAN V. TAFRESHI, ALENKA LUZAR, Virginia Commonwealth University — The interaction of droplets with a surface is crucial in engineering applications such as coating, air filtration, and liquid transport in microfluidic devices. Despite recent advances in fluid mechanics and surface science, the mechanism of droplet detachment from the surface and the amount of residue left behind are not formulated well. When the droplets are forcibly removed from a surface, the ease of detachment strongly depends on the droplet volume and the rate of the removal. Experiments and continuum level calculations have so far been unable to resolve the time-dependent dynamics of droplet detachment and the role of the applied force as the key determinant of the volume of the droplet residue on the surface. We present a comprehensive study for predicting the force required to detach the water droplet from a graphene surface through the Molecular Dynamics (MD) simulations. Our results show that the minimum detaching force (per unit mass) decreases with the volume of the droplet and increases with the strength of water-surface adhesion. We also determined the amount of residue on the surface after detachment for different forces and water-carbon interactions. We observed that as the droplet size increases, a bigger residue remains on the surface. We found that the maximum amount of residue can be observed by applying the minimum force of detachment in contrast to experimental and MD results for droplet detachment from the curved surfaces where intermediate force was found to maximize the water retention.

4:40PM G41.00005 A reduced order model for prediction of aerodynamic loads on an unmanned aerial system with hybrid quadcopter biplane configuration, MORTEZA HEYDARI, HAMID SADAT, University of North Texas — Army Research Lab (ARL) has recognized Unmanned Aerial Systems (UAS) with Vertical Take-Off and Landing (VTOL) to be capable of delivering paramount tasks such as intelligence, surveillance, electronic attack, etc. in the future. Advances in manufacturing and material technologies have opened a new design space for novel VTOL UAS configurations but significant knowledge gaps still exist to design a configuration which can achieve the desired performance. ARL designed research VTOL UAS platforms called Common Research Configuration (CRC) with hybrid quadcopter biplane concept to enable a comprehensive study on such aircraft. Inherent to all VTOL UAS such as CRC platforms is the need for a transition from hover to forward flight and forward flight back to hover throughout a mission. This transition produces highly non-linear loads on the wings due to the rotor-wing interactions and may present a significant challenge for robust control. The aim of this study is to develop a reduced order model (ROM) capable of predicting loads on CRC-3, the smallest size of the CRC generation with 3lb weight. A set of data obtained from hundreds of CFD simulations for a wide range of conditions are used as the training set for a neural network. The predicted loads by the developed ROM show good agreement with the test set. Additional data from the dynamic body equations are coupled with the ROM to investigate the CRC-3 flight dynamics. CFD simulations are conducted using our in-house solver, CFDFoam.
4:53PM G41.00006 Simulation of three dimensional aeronautical flow using the SED-SL algebraic turbulence model. 1, 2  TAN-TAN DU, MENG-JUAN XIAO, WEI-TAO BI, ZHEN-SU SHE, Peking Univ. — The SED-SL model specifies a multilayered stress length (SL) function in the wall-normal direction (which depicts the eddy viscosity), with slowly varying parameters along the streamwise direction simulating the entire turbulent boundary layer (TBL) including transition. After successful simulations of transitional flat-plate (APS meeting, 2016), airfoils (APS meeting, 2017), and 3-D aeronautical flows (APS meeting, 2018), here we report an in-depth study of the SED-SL model in simulating flows over M6 wing and DLR-F4 wing-body. For the M6 wing, intuitive consideration suggests a mildly varying buffer layer thickness in the spanwise direction, yielding a more accurate prediction of the shock locations and their merging above the wing surface, and thus a better prediction of the aerodynamic forces than those of the S-A and SST models. A comparison with a large eddy simulation of the flow shows also a superior prediction of the flow structures and Reynolds stress distribution. For the DLR-F4 wing-body, a significant improvement also is obtained with the new model compared to the SA and SST, in the prediction of the flow structures near the wing-body juncture and wing tip. These results demonstrate that the SED-SL model captures the right and simple (multilayer) structure of TBL, and is adaptable to aeronautical flows with not only high accuracy and efficiency for assisting design, but also more knowledge about the flow physics.

5:06PM G41.00007 Computational Investigations of Flow Past Axially Aligned Rotating Cylinders1, 2, 3 IGBAL MEHMEDAGIC, PASQUALE CARLUCCI, LIAM BUCKLEY, DONALD CARLUCCI, U. S. Army ARDEC, Picatinny Arsenal, NJ, SIVA THANGAM, Stevens Institute of Technology, Hoboken, NJ — Projectiles with free spinning segments are often used in smart munitions to provide effective control, stability and target guidance. Computational investigations are performed for flow past cylinders aligned along their axis where either the middle or base segment freely spins while attached to a non-spinning fore and/or aft body. The energy spectrum is modified to incorporate the effects of swirl and rotation using a parametric characterization of the model coefficients. An efficient finite-volume algorithm is used to solve the time-averaged equations of motion along with the modeled form of transport equations for the kinetic energy and the scalar form of turbulence dissipation. Experimental data for a range of spin rates and free stream flow conditions obtained from subsonic wind tunnel for flow past axially aligned cylinders with spinning segments are used to validate the computational findings.

5:19PM G41.00008 Optimization of Pressurized Water Reactor Size and Coolant Flow Rate1, 2 SCOTT WAHLQUIST, Student, BRYAN LEWIS, Professor — In nuclear reactors, the heat generated in the system must be removed as fast as it is produced to operate in steady state. To accomplish this, liquid or gaseous coolant is moved through the core with pumps. In a typical pressurized water reactor (PWR), the standard inlet temperature is 290°C and the standard outlet temperature is 325°C. Using RANS modeling, a heat transfer CFD analysis was conducted on a basic structure of a PWR (neutron shield panel, nuclear core, and vessel wall) to show how water flows through the reactor and to determine the volumetric flow rate that creates the necessary convection to produce the inlet and outlet water temperature differential. The reactor was then scaled and the simulation was then repeated to observe the change in required flow rate. A plot comparing the size of the reactor to the required volumetric flow rate was made to determine the minimum and maximum reactors sizes with volumetric flow rates that don’t exceed the max allowable flow rate of a typical PWR pump and still produces the outlet temperature.

Session G42 Boundary Layers: Wind Turbine Interactions I 6e - Nicholas Hamilton, National Renewable Energy Laboratory

3:48PM G42.00001 Data Assimilation for the Prediction of Wake Trajectories Within Wind Farms1, 2 MAXIME LEJEUNE, Universite catholique de Louvain (UCLouvain), MARION COQUELET, UCLouvain - U Mons, NICOLAS COUDOU, UCLouvain - U Mons - VKI, MAUD MOENS, PHILIPPE CHATELAIN, Universite catholique de Louvain (UCLouvain) — Wind turbine wake physics is by nature unsteady and highly sensitive to the local wind characteristics. While Large Eddy Simulations (LES) allow to accurately capture the flow at the wind farm scale for a wide range of atmospheric conditions, they still come at a prohibitive computational cost when it comes to online control. Based on the Dynamic Wake Meandering model, the presented model couples a meandering model and a wake speed deficit model in order to estimate the velocity field downstream the wind turbine. Focus is laid on limiting the number of input parameters by building on recent advances in flow sensing to feed the wake model with estimated inflow conditions. The remaining parameters are fine-tuned through online data assimilation techniques, thus adapting to inflow conditions. The performances of the resulting wake model are assessed using data recovered from high fidelity LES simulations.

4:01PM G42.00002 Analytical model for yawed turbine asymmetric wakes. 1, 2, 3 MICHELE GUALA, St. Anthony Falls Laboratory, CEGE, University of Minnesota, BINGZHENG DOU, LIPING LEI, PAN ZENG, Department of Mechanical Engineering, Tsinghua University — Due to large scale atmospheric variability and slow nacelle adjustments, wind turbines are predominantly operating in yawed conditions. In addition, to minimize turbine-turbine interactions and maximize spatially averaged energy production in wind power plant arrays, the yaw angle becomes a control variable for operators to steer the wake of front row units away from downwind rotors. Both mechanisms are expected to be relevant also for Marine Hydrokinetic (MHI) Turbines, experiencing large scale variability due to migrating bedforms in fluvial or tidal flows. We present a new wake model able to predict the location of the maximum velocity deficit, and the asymmetric distribution of the mean velocity about the wake center, for different downwind distances (Dou et al., 2019). The model has been calibrated using wind tunnel and open channel flow experiments with yawed miniature turbines of different shape, size and operating conditions. The key advantages of the proposed wake model are: i) the model requires only the thrust coefficient in un-yawed conditions, ii) the required parameter describing the wake expansion has been observed to be weakly depending on specific incoming flow condition, iii) the parameter describing the wake asymmetry can be estimated based on the yaw angle and the thrust coefficient. Thus, input parameters of the proposed model are for the most part limited to the turbine geometry, its operating conditions, and the associated thrust coefficient.
A simplified DWM model are compared with the LES results. To evaluate Taylor's frozen-flow hypothesis using the LES data of turbine wakes. The space-time correlations are examined. The predictions from our knowledge, the validity of Taylor's frozen-flow hypothesis for modeling wake meandering has not been fully evaluated. In this work, we have developed a meandering (DWM) model has been developed in the literature (Risø National Laboratory Technical Report, 2007, Risø-R-1607). In the DWM simulation (LES), which is able to predict the energetic coherent structures of turbine wakes, on the other hand, cannot be directly applied to the design of wind farms because of its high computational cost. To fast predict the meandering motion of turbine wakes, the dynamic wake meandering (DWM) model has been developed in the literature (Risø National Laboratory Technical Report, 2007, Risø-R-1607). In the DWM model, the meandering motion is taken into account by modeling wakes as passive scalars based on Taylor's frozen-flow hypothesis. To the best of our knowledge, the validity of Taylor's frozen-flow hypothesis for modeling wake meandering has not been fully evaluated. In this work, we evaluate Taylor's frozen-flow hypothesis using the LES data of turbine wakes. The space-time correlations are examined. The predictions from a simplified DWM model are compared with the LES results.

8:00AM H01.00001 Dominant Resonance in Parametric Subharmonic Instability of Internal Waves

REZA ALAM, YONG LIANG, LOUIS-ALEXANDRE COUSTON, QIUCHEN GUO, UC Berkeley — Parametric Subharmonic Instability (PSI) is one of the most important mechanisms that transfer energy from tidally-generated long internal waves to short steep waves. Breaking of short waves results in diapycnal mixing through which oceanic abyssal stratification is maintained. It has long been believed that PSI is strongest between a primary internal wave and perturbative waves of half the frequency of the primary wave. Here, we show that this is not the case. Specifically, we show that neither the initial growth rate nor the maximum long-term amplification occur at the half frequency, and demonstrate that the dominant subharmonic waves have much longer wavelengths than previously thought.

8:13AM H01.00002 Resonance and transmission of axisymmetric internal wave modes

PHILIPPE ODIER, SAMUEL BOURY, Laboratoire de Physique, Ecole Normale Superieure de Lyon, France

THOMAS PEACOCK, Department of Mechanical Engineering, MIT, USA — To date, axisymmetric internal wave fields, relevant to atmospheric waves generated by storm cells and oceanic near-inertial waves produced by surface perturbations, have been experimentally produced using an oscillating sphere or torus as the source. Here, we use a wave generator configuration capable of exciting axisymmetric internal wave modes of arbitrary radial form. The efficiency of the wave generator is measured through careful estimation of the wave amplitude based upon group velocity arguments, and the effect of vertical confinement is considered to induce resonance, identifying a series of experimental resonant peaks agreeing well with theoretical predictions. In the vicinity of resonance, the waves undergo a transition to nonlinear behavior. In a second step, we investigate transmission of these modes in nonlinear stratifications. Two configurations are studied: in the case of a free incident wave, a transmission maximum is found in the vicinity of evanescent frequencies. In the case of a confined incident wave, resonant effects lead to enhanced transmission rates from upper to lower layer. We consider the oceanographic relevance of these results by applying them to an example oceanic stratification from the Arctic, finding that there can be real-world implications.

8:26AM H01.00003 Numerical Simulations of the Internal Waves Produced by a Submerged Body in a Stratified Fluid

LAURA BRANDT, DEVIN CONROY, JAMES ROTTMAN, Leidos — We attempt to gain some insight into the modeling of internal waves produced by a submerged body traveling horizontally at high Reynolds number in a strongly stratified fluid by comparing numerical simulations with linear theory. Two types of internal waves are generated by the horizontal motion of a body in a stratified fluid: lee waves, which are steady in a reference frame moving with the body and are generated by the motion of the body itself, and wake waves, which are unsteady and generated by the turbulent wake. Traditionally the lee waves have been represented in linear theories by a source singularity in the continuity equation, but recently it has been argued that a body force needs to be added to the momentum equations in order to accurately represent the lee waves. We test this latter hypothesis directly by comparing linear theory with our numerical simulations in which either a free-slip or no-slip boundary condition at the surface of the body is imposed. The free-slip boundary condition represents a body with no downstream recirculation region, so the source singularity should be accurate, and the no-slip boundary condition would have a downstream recirculation region, so that the body force should be necessary.

8:39AM H01.00004 Linear and nonlinear fate of an axisymmetric inertial wave attractor

SAMUEL BOURY, THIERRY DAUXOIS, SYLVAIN JOUBAUD, PHILIPPE ODIER, Univ Lyon, ENS de Lyon, Univ Claude Bernard, CNRS, Laboratoire de Physique, F-69342 Lyon, France

EVENY OGREN, University of Gothenburg, Sweden

KUNIHIRO SUGIURA, University of Tokyo, Japan

Iliyas Sibgatullin, Lomonosov Moscow State University, Moscow, Russia — For a few decades now, numerous studies have been devoted to the properties of inertia-gravity wave reflection. Since the angle of propagation of these waves is set by the ratio of their frequency to the buoyancy or rotation frequency, the reflection on a wall does not follow the usual Snell-Desartes law. In particular, in a confined trapezoidal domain, the wave beam experiences a focusing effect and eventually ends on a limit trajectory called attractor. Experimental and numerical studies have shown evidence of this phenomenon for internal waves in 2D geometry. Due to the local energy focusing, nonlinear triadic cascades occur in the branches of the attractor, leading to energy transfer between scales. More recently, geometric and 3D aspects of internal wave attractors have been explored using Direct Numerical Simulations of inertial waves. The DNS pictured an axisymmetric inertial wave attractor, in a trapezoidal cylindrical domain, with focusing and defocusing effects caused by wave reflections and by the radial geometry itself. Wave instability occurs while forcing the attractor and leads to an azimuthal symmetry breakdown. Using an apparatus relevant for axisymmetric wave generation, we produce an inertial wave attractor in a cylindrical domain and we explore its properties.

8:52AM H01.00005 Modal decomposition of polychromatic internal wave fields in arbitrary stratifications

MORRIS FLYNN, University of Alberta, ALEXIS KAMINSKI, Applied Physics Laboratory, University of Washington — Internal waves e.g. those produced by tidal sloshing over bathymetry play a crucial role in the energetics of the oceanic overturning circulation. Understanding their spatial and temporal structure, which depend on both the details of the forcing topography and the forcing frequency, is essential in predicting where mixing may occur, details of which remain poorly understood. Past work has largely focused on the case of a monochromatic wave-field; however, tides are composed of multiple frequency constituents. Here we present an approach by which the modal structure of a polychromatic internal wave-field may be computed from velocity data without any a-priori knowledge of the details of the forcing topography. We consider wave-fields in both uniform and vertically-varying stratification, and show using synthetic data that our approach is able to accurately reconstruct the vertical mode strengths. The sensitivity of our approach to noise and vertical resolution is also examined.

1NSERC
The instabilities of spatially monochromatic internal waves have been well-studied in the past decades, owing to their fundamental nature and relevance to geophysical processes. On the other hand, internal wave beams with locally confined spatial profile have only recently gained appreciation for their distinct properties and instability mechanisms. Such wave beams provide a more realistic setting for the study of internal wave instabilities in the ocean as they naturally arise, for instance, from the interaction of the barotropic tide with bottom topography. Owing to their additional complexity, internal wave beam instabilities have thus far been analyzed primarily in weakly nonlinear contexts, with the most famous being the parametric subharmonic instability. Here, we instead investigate the stability of finite-amplitude internal wave beams to two-dimensional perturbations using Floquet theory. We then compare these theoretical results with novel experimental observations.

Experimental results on the long-time spatial and temporal development of Triadic Resonance Instability

Various mechanisms have been proposed to explain how internal waves transfer energy across the wavenumber and frequency spectrum and eventually contribute to small-scale turbulence and mixing. Triadic Resonance Instability (TRI) has become increasingly recognized as one of these mechanisms. This talk will focus on new experimental investigation into the temporal and spatial evolution of this instability. Experiments have been conducted using a wave tank set-up, featuring a flexible horizontal boundary condition which is driven by an array of independently controlled actuators. This allows for varying amplitude, frequency and wave-length in both the spatial and temporal domain. We present results utilizing this ability to vary the forcing parameters during the course of an experiment and investigate what effects this has on the evolution of TRI.

Large internal waves in deep water: models, numerics and experiments

We investigate the propagation of large solitary internal waves in continuously salt-stratified water close to homogeneous two-layer configurations. When the lower, denser layer is much deeper than the one at the top. Experiments are performed in the UNC wave tank, with data collected via PIV and LIF, from both fixed locations and by a cart moving with the waves. Predictions from an optimized two-layer fully nonlinear model are compared with the experiments and direct numerical simulations of Euler equations in two dimensions.

Joint effects of topography and rotation in internal solitary waves

An asymptotic, adiabatic theory for the evolution of an internal solitary wave governed by the variable-coefficient, rotation-modified Gardner equation (Korteweg-de Vries with cubic nonlinearity) is developed and used to explore the joint effects of variable topography and rotation on the evolution of this instability. Experiments have been conducted using a wave maker, featuring an array of independently controlled actuators. We then compare these theoretical results with novel experimental observations.

1Supported by the Office of Naval Research grant N00014-18-1-2542.

Examining the initial development of convective instability in a three-dimensional shoaling internal solitary wave of depression in over gentle slopes

A convectively unstable internal solitary wave (ISW) of depression, shoaling over gentle slopes (<3%), is examined through fully nonlinear and non-hydrostatic simulations. These simulations are based on a high resolution/accuracy deformed spectral multidomain penalty method flow solver. The convective instability occurs due to a sudden increase in the propagation speed, below the maximum horizontal wave induced velocity, the wave retains its nearly symmetric shape as it shoals. Subsequently, an unstable region develops characterized by the entrainment of heavier-over-light fluid, in the form of a recirculating, or trapped, core. The preceding convective instability is attributed to the stretching of the near-surface vorticity layer of the baroclinic background current from the propagating ISW. According to recent field observations in the South China Sea, this region may persist for more than 10 km and drive turbulent-induced mixing, estimated to be up to four times larger than that in the open ocean. Motivated by such observations, emphasis in this presentation is placed on the onset of the 3D convective instability as the ISW shoals. The ISW propagates in the normal-to-isobath direction. The initial 3D instability is visualized via a transitional structure that develops in the lateral direction. The evolution of the lateral instability is compared with the convective overturn of the core. As such, a preliminary understanding of the formation of recirculating cores in ISWs is obtained.

10:10AM H01.00011 Propagation and Breaking of Three-Dimensional Boussinesq Wave Packets without and with Rotation

1, ALAIN GERVAIS, Department of Mathematical and Statistical Sciences, University of Alberta, Canada, QUINLAN EDE, Department of Earth and Atmospheric Sciences, University of Alberta, Canada, GORDON SWATTERS, Department of Mathematical and Statistical Sciences, University of Alberta, Canada, TON VAN DEN BREMER, Department of Engineering Science, University of Oxford, United Kingdom, BRUCE SUTHERLAND, Departments of Physics and of Earth and Atmospheric Sciences, University of Alberta, Canada — Internal gravity waves (IGWs) propagate vertically and horizontally within stably stratified fluids. As IGWs propagate vertically, nonlinear processes lead to instabilities that may cause a wave to overturn and eventually break, thus irreversibly depositing momentum to the background flow. Even before breaking, moderately large amplitude IGWs induce a mean flow that interacts nonlinearily with the waves, Doppler-shifting their frequency and altering the height at which the waves would have otherwise overturned. Here we derive explicit formulae for the induced flows of localised wavepackets influenced by Coriolis forces. Numerical simulations are initialised with quasi-monochromatic wave packets with the predicted induced flow superimposed. Simulations with small amplitude wave packets confirm that the prediction captures the induced flow. In simulations with larger amplitude waves, the nonlinear interactions between the waves and the flows they induce result in much lower overturning heights than predicted by linear theory.

8:39AM H02.00004 Cavitation dynamics in the wake of a backward facing step¹. ANUBHAV BHATT, HARISH GANESH, STEVEN L. CECCIO, University of Michigan, Ann Arbor, MI-48109 — The flow over a backward facing step is often used as a benchmark for experimental studies on separation and reattachment in hydrodynamic applications. The flow has a separating and reattaching shear layer forming a recirculating region. These shear layers are susceptible to cavitation, and can experience different dynamics depending upon the extent of the cavitation formed in the shear layer and contained within the recirculation bubble. Beginning with cavitation inception, a reduction in cavitation number results in different cavitation regimes such as fully developed cavitation, self-sustained cloud shedding and super-cavitation. This study focuses on quantifying the cavitation dynamics of the developed cavitation, at three Reynolds numbers (8.5*1E4, 10.6*1E4 and 12.7*1E4) using time-resolved X-Ray densitometry and high speed videography. In addition, static and unsteady pressure measurements are performed to understand the change in dynamics within the region of flow separation. The effect of compressibility of the vapor-liquid mixture is assessed by estimating the speed of sound based on the static pressure and void-fraction measurements at different cavitation conditions.

8:52AM H02.00005 Investigation of turbulent cavitating flows in a small Venturi by fast X-ray imaging. GUANGJIAN ZHANG, Arts et Metiers ParisTech, MINMING GE, Virginia Tech, ILYASS KHLIFA, Arts et Metiers ParisTech, OLIVIER COUTIER-DELGOSHA, Virginia Tech — The cavitating flows created in a small Venturi nozzle are investigated based on ultra-fast x-ray imaging. The instantaneous velocities of the liquid and vapor are measured simultaneously by tracking seeding particles and vapor structures respectively while the vapor volume fraction is derived from the different x-ray attenuation. Wavelet decomposition with appropriate thresholds is used to separate seeding particles from vapor structures, so that image cross-correlations could be applied on the two phases separately. This study presents data on mean velocity and void ratio field, statistical turbulent quantities in three different cavitation levels with the same reference velocity. A type of cavitation associated with a weak but persistent re-entrant jet is described. The comparison between the cavitation and the non cavitation flow field shows that the averaged flow field is significantly altered by the presence of cavitation and the vapor formation near the throat area is observed to suppress velocity fluctuations.

9:05AM H02.00006 Thermodynamic effects on Venturi cavitation characteristics¹. ZHIGANG ZUO, HAOCHEN ZHANG, Tsinghua Univ., KNUD AAGE MRCH, Technical Univ. of Denmark, SHUHONG LIU, Tsinghua Univ. — In studies using cold water as the working liquid, the thermodynamic effect of cavitation is usually ignored. However, in cryogenic liquids, refrigerants and high temperature water the thermodynamic effect is significant, and it suppresses the development of cavitation by reducing the temperature at the boundary of expanding cavitation bubbles. In this paper the thermodynamic effect is systematically studied by Venturi cavitation in a blow-down type tunnel for the first time, using water at temperatures up to relatively high levels, and at controlled dissolved gas content in the supply reservoir (measured by dissolved oxygen, DO). The cavitation characteristics are analyzed from the experiments, and the mean cavitation length is chosen as the quantity suited to reveal the thermodynamic effect. With an increase of the thermodynamic parameter, a decrease of cavitation length is observed, which is consistent with suppression of cavitation by the thermodynamic effect. Within the range of DO content tested, the DO content has little influence on the mean cavitation length and the unsteady cavitation characteristics, which is in contrast to the effect of gas content on cavitation nuclei generally.

¹The work was supported by National Natural Science Foundation of China (No. 51479083), National Basic Research Program of China (No. 613321), State Key Laboratory of Hydro Science and Engineering (Research Fund Programs, No: 2017-KY-03 and 2019-KY-04), and the Otto Muensted Foundation (Grant 15-81-1166).

9:18AM H02.00007 Thermal effects in cavitating flows. MARTIN PETKOVSEK, University of Ljubljana, DREW JACOBS, MINMING GE, OLIVIER COUTIER-DELGOSHA, Virginia Tech — The effects of temperature on hydrodynamic cavitation in water is investigated. Temperature is varied between 20C and 85C in a cavitating flow generated in a small-scale venturi type section of 1 mm characteristic dimension. The effects of the temperature on the large-scale periodical cloud shedding is investigated, as well as the evolution of the flow structure and dynamics. The measurements are based on high speed visualizations and 2D2C PIV. A competition between two different effects, namely the Reynolds number change and the cavitation delay due to the so-called thermal effect, is observed. A critical temperature in the range 50C-60C is found and especially investigated.

9:31AM H02.00008 Control of cavity bubble in water entry using laser-induced cavitation. KYUSEONG CHOI, NAYOUNG KIM, GUWON SEON, WONTAE HWANG, HYUNGMIN PARK, Seoul National University — We investigate how the cavity attached to the metallic sphere in water entry changes when laser is irradiated. The sphere (radius, R=1, 2mm) is roughened (0.1-1µm in size) to generate a cavity even at a relatively low impact speed (Uo=1.5-3.3m/s). By varying the height of dropping position and irradiation time, that is speed and surface temperature (To=110-350°C) at the impact instant, we measure the cavity dynamics with a high-speed camera (the water is at room temperature). In the case of a shallow seal (R=1mm, Uo=1.5m/s), we classify two regimes of cavity growth (To=170-240°C) and destruction (To=240°C). In the destruction regime, microbubble emission boiling happens, so the cavity is destructed to numerous microbubbles. In the case of a deep seal (R=1mm, Uo=3.3m/s), the slight cavity growth occurs at To=130-150°C and considerable destruction of cavity bubble at To=170°C. At a transient of To=150-170°C, the deep seal changes to shallow seal with a slight destruction of cavity. As a change of cavity dynamics, the forces acting on the sphere is varied, which is estimated from measured cavity geometry and sphere trajectory. Finally, we suggest a mechanism of cavity growth and destruction according to Uo and To.

9:44AM H02.00009 Air entrainment mechanisms of a forced plunging jet¹. SOPHIA RELPH, KEN KIGER, University of Maryland, AKASH DHURV, ELIAS BALARAS, George Washington University — Plunging jets play a major role in the quality of cast metal parts, as the pouring process can entrain metal oxides in much the same way as pouring water captures bubbles. These air and oxide pockets interfere with the metals crystal structure and can compromise strength and fatigue life. The mitigation of such defects is of great interest to foundries. Most research on plunging jets relevant to metal casting considers either smooth or passively disturbed jets that result from a turbulent nozzle state, with little characterization beyond the variance of the velocity. We know that at higher velocities, defects is of great interest to foundries. Most research on plunging jets relevant to metal casting considers either smooth or passively disturbed jets that result from a turbulent nozzle state, with little characterization beyond the variance of the velocity. We know that at higher velocities, jet disturbances play a large role in air entrainment, but the literature is inconclusive on the mechanism by which this occurs. The current work examines the role of carefully controlled forced disturbances on both a plunging jet and the pool surface, allowing us to correlate surface disturbance properties with air entrainment behavior. The current effort is focused on determining the size (wavelength and amplitude) of the disturbances, as well as the relative phaseing, on controlling the inception of air entrainment and the volume of the resulting air entrainment events. Results from a laboratory-scale air/water experiment and corresponding DNS will be presented.

Homogeneous Equilibrium Mixture (HEM) Cavitation Model. JOSHUA BRINKERHOF, SAEED RAHBARIMANESH, University of British Columbia; IOANNIS KARATHANASSIS, MANOLIS GAVAISES, City, University of London — The commonly-used homogeneous equilibrium mixture (HEM) cavitation models lack accurate treatment of two phase flow properties at mixture saturation states, which leads to miscalculation of pressure and density in computational fluid dynamics (CFD) simulations. This issue can be addressed by employing a reliable barotropic equation of state (EOS) in the cavitation model. The current study presents a piecewise EOS that can accurately capture flow properties at liquid, vapor, and transition states. Implementing the proposed EOS in a HEM solver to simulate the cavitating flow of diesel in a throttle shows a better match against mass flow rates measured in experiments than a single-step EOS approach. The improvement is due to the enhanced functionality of the solver in relaxing sharp pressure and density gradients during condensation and vaporization processes. The lack of such capability in the single-step model seems to cause additional numerical diffusion in shear layers and interface regions, particularly in areas with stronger condensation, resulting in poorly predicted cavitation. The work is a step towards the main objective of improving HEM cavitation modeling in CFD of cryogenic fluids.

10:10AM H02.00011 Numerical study of cavitating flows around an immersed solid body.1. GIHUN SON, SEONGJIN HONG, Sogang University — A numerical approach is presented for cavitating flows around an immersed solid body. The single-fluid model for cavitating flows, which is based on a barotropic relation between fluid density and pressure variations in the liquid-vapor phase-change region, is coupled to a fictitious-domain (FD) method, where the immersed solid region is assumed to be filled with the surrounding fluid with a high viscosity. The FD method can be efficiently applied to complex body geometries without generating body-fitted meshes and does not need an explicit calculation of forces and torques acting on the solid boundary unlike immersed boundary methods. The conservation equations of mass and momentum with the compressibility effect in the cavitation region are solved by employing a projection method and a semi-implicit pressure correction method to avoid the serious time step restriction in weakly compressible flows. The present numerical method combined with a non-equilibrium k-ε turbulence model is tested through computations of cavitating flows around a hemispherical body and a wedge-shaped body, whose numerical results or experimental data are available in the literature. The numerical method is extended for cavitating flows around a moving solid body.

10:23AM H02.00012 Gelatin cavity dynamics in the wake of high-speed solid sphere impact.1. AKIHITO KIYAMA, Tokyo University of Agriculture and Technology, MOHAMMAD MANSOOR, NATHAN SPEIRS, Utah State University, YOSHIYUKI TAGAWA, Tokyo University of Agriculture and Technology, TADD TRUSCOTT, Utah State University, TUAT COLLABORATION, USU COLLABORATION — We investigate the impact and penetration of a small solid sphere onto gelatin at speeds greater than 100 m/s. High-speed videography allows us to capture the cavity dynamics in the wake of the sphere. Varying the gelatin concentrations affects the elastic response of the medium. The high-speed videography reveals several unique features of the cavity dynamics in gelatin when compared to water (e.g., the appearance of the texture on the wall of gelatin cavity, the attenuation of the vertical jet upon the pinch-off of gelatin cavity). We present a phase diagram that classifies the cavity pinch-off type using the elastic Froude (inertia vs. elasticity) and the elastic Grashof (gravity vs. elasticity) numbers (Akers & Belmonte, J. Non-Newtonian Fluid Mech., 2006), similar to the Weber and Bond numbers used for water entry (Aristoff & Bush, J. Fluid Mech, 2009). We also discuss the detailed dynamics of each cavity type based on high-speed images.

Session H03 Focus Session: Direct Numerical Simulations of Fluid Interfaces, Deformation and Break-Up in Turbulence 201 - Olivier Desjardins

8:00AM H03.00001 DNS of turbulent flows laden with deformable bubbles or droplets: Overview of methods. SAID ELGHOBASSI, University of California, Irvine — Turbulent flows laden with liquid droplets or gas/vapor bubbles are ubiquitous in nature and engineering applications. In nature, examples include rain, air bubbles in the upper ocean, and vapor bubbles in geysers. Engineering applications include liquid fuel sprays in all types of combustion engines, paint sprays, spray drying in the pharmaceutical industry as well as food processing, and water vapor bubbles in nuclear reactor cooling systems or those created by cavitation in the wakes of ship propellers, just to list a few. This lecture focuses on direct numerical simulations (DNS) of turbulent flows laden with droplets or bubbles. DNS of these flows are more challenging than those of flows laden with solid particles due to the surface deformation in the former. The numerical methods to be discussed are classified by whether the initial diameter, d, of the bubble/droplet is smaller or larger than the Kolmogorov length scale, η. The lecture discusses DNS of deformable small spherical bubbles/droplets (d < η) via a phenomenological model.[1]

8:13AM H03.00002 DNS of turbulent flows laden with deformable bubbles or droplets: Recent advances. SAID ELGHOBASSI, University of California, Irvine — Turbulent flows laden with liquid droplets or gas/vapor bubbles are ubiquitous in nature and engineering applications. In nature, examples include rain, air bubbles in the upper ocean, and vapor bubbles in geysers. Engineering applications include liquid fuel sprays in all types of combustion engines, paint sprays, spray drying in the pharmaceutical industry as well as food processing, and water vapor bubbles in nuclear reactor cooling systems or those created by cavitation in the wakes of ship propellers, just to list a few. We discuss recent advances in the numerical methods[1] of deformable large spherical bubbles/droplets whose initial sizes are larger than the Kolmogorov length scale, η. The methods include the Conservative Level Set (CLS), Volume of Fluid (VOF), Front Tracking (FT), Phase Field Model (PFM), and Lattice Boltzmann (LB).

8:52AM H03.00005 Direct numerical simulation of bubble-induced turbulence at high Reynolds number, ALICE JACCOD, Sorbonne Universite, ALESSIO INNOCENTI, Istituto Nazionale di Geofisica e Vulcanologia, STEPHANE POPINET, SERGIO CHIBBARO, Sorbonne Universite — Among the various kind of multiphase flows, bubbly flows represent a challenging and key field of investigation for their particular dynamics and their applications in several fields. Important experiments have been carried out in the last decades but a precise understanding of bubble-induced turbulence is still lacking. In the present work, a study of this phenomenon is presented, by performing fully resolved two and three dimensional numerical simulations of bubbles, rising up under the effect of buoyancy. Bubbles, initially placed at rest at the bottom of a channel, experience a large transfer rate with the liquid, resulting in an agitated turbulent motion, called pseudo-turbulence. Varying the physical parameters of the problem as the bubble volume fraction and increasing the Reynolds number, it's possible to outline a large phenomenology of the dispersed phase flow. An investigation of energy spectra and velocity fluctuations probability density function has been done, for both two and three dimensional cases. Moreover, we performed a scale-by-scale analysis of energy transfer, to identify the spatial scale within which a direct or inverse energy cascade is present.

9:18AM H03.00007 Breakup at the resolution limit, MARCUS HERRMANN, Arizona State University — The process of atomization is characterized by a vast range of time and length scales present in the flow. In fact, when the topological change of the phase interface occurs, i.e. a liquid structure breaks into smaller structures, the length scale goes to zero. Thus simulations of atomization are not able to resolve all length and time scales at all times. Typically, simulations are under-resolved during the final stages of breakup, relying on the properties of the numerical methods used, i.e., the properties of the methods’ inherent numerical errors, to capture the topology change events correctly. This reliance on numerical errors to reproduce physical processes is questionable, but unavoidable without dedicated, breakup models that do not rely on the local mesh resolution to initiate breakup. In this talk, we will discuss how different interface capturing techniques perform during the final stages of breakup, using the breakup of a ligament in a test bed as an example. The results can give insights into the drop size distributions obtained in detailed simulations of atomizers, especially concerning smaller drop sizes near the mesh resolution limit.

9:31AM H03.00008 Lattice Boltzmann Simulations of Interface Deformation and Breakup in Turbulent Flow Over Superhydrophobic and Liquid-Infused Surfaces1, AMIR-REZA RASTEGARI, RAYHANEH AKHAVAN, The University of Michigan — Interface deformation and breakdown in turbulent flow over Super-Hydrophobic (SH) and Liquid-Infused (LI) surfaces is investigated by Direct Numerical Simulation (DNS) using a two-phase, single relaxation time, free-energy lattice Boltzmann method. In this method, the dynamics of a diffuse interface is incorporated into the governing equations using a Peng-Robinson free-energy functional. This obviates the need for explicit tracking of the interface or pinning of the contact line. DNS studies were performed in turbulent channel flows with longitudinal microgrooves of width $15 \leq g^{1/10} \leq 64$ in base flow units, at solid fractions of $\phi_s = 1/16$ or 1/2 on both walls. Simulations were performed at a base flow friction Reynolds number of $Re_T \approx 222$, with viscosity ratios of $\mu_{ext}/\mu_{int} = 10$, 20 and 55, and Weber numbers of $10^{-3} \leq We_r \leq \mu_{ext}/\sigma \leq 10^{-2}$. Analysis of the results shows that interface deformation and contact line motion can significantly reduce the magnitude of drag reduction compared to DNS results obtained in turbulent flow with 'idealized', flat SH or LI interfaces. In addition, the simulations identify the conditions for contact line depinning and interface breakdown.

The non-zero inlet angle is shown to impact small-scale interfacial wave formation and breakup. Wavelet analysis is performed to the macro-scale jet dynamics, such as jet deflection and asymmetric deformation of the head of liquid jet. The simulations results of the global through high-fidelity simulation. The non-zero inlet angle induces an azimuthal variation of velocity in the liquid jet, which in turn influences many fuel injection applications, the liquid flow direction at the nozzle inlet is not perpendicular to the inlet plane. The effect of the angle is generally considered to be aligned with the nozzle axis. As a result, the near-field instability development is axisymmetric. Nevertheless, in many fuel injection applications, the liquid flow direction at the nozzle inlet is not perpendicular to the inlet plane. The effect of the angle between the inlet velocity and nozzle axis on the primary breakup of a round liquid jet is unclear and will be investigated in the present study through high-fidelity simulation. The non-zero inlet angle induces an azimuthal variation of velocity in the liquid jet, which in turn influences the macro-scale jet dynamics, such as jet deflection and asymmetric deformation of the head of liquid jet. The simulations results of the global features, including jet deflection angle and temporal evolution of penetration length, are compared with experimental data and good agreement is achieved. The non-zero inlet angle is shown to impact small-scale interfacial wave formation and breakup. Wavelet analysis is performed to characterize the azimuthal variation of the interfacial waves in the near field.

10:10AM H03.00011 Characterizing the dynamics of complex multiphase flows undergoing topology changes. GRETAR TRYGGVASON, JIACAI LU, Johns Hopkins University — Although disperse multiphase flows, where one fluid appears as discrete drops or bubbles dispersed in another contiguous phase, have been widely studied, such flows are generally only seen when the volume fractions of the fluids are very different. For comparable void fractions, particularly if the fluid is turbulent, we expect to see a complex dynamic interface whose topology changes repeatedly as fluid masses coalesce and break apart. Describing and modeling such churn-turbulence flows is challenging. Approaches drawn from studies of heterogeneous solids, rheology, and premixed combustion provide some guidance, but do not cover the full complexities of a dynamic interface and fluid turbulence. The challenges involve both finding the appropriate statistical descriptions as well as the generation of coarser models. We discuss these challenges; review the various ways the flow can be described and modeled; and show examples from our recent work on complex turbulent buoyant two fluid flows in vertical channels and the breakup of periodic liquid jets.

1 Supported by DoE/CASL.

10:23AM H03.00012 Simulating high void fraction flows undergoing massive topology changes in vertical channels. JIACAI LU, GRETAR TRYGGVASON, Johns Hopkins University — Turbulent multiphase flows in vertical channels, where the topology of the interface between the different fluids repeatedly changes due to the breakup and coalescence of fluid masses, are examined by numerical simulations, using a finite volume/front-tracking method where the interface is tracked by connected marker particles and the flow equations solved on a regular structured grid. When a film of one fluid, separating blobs of a different fluid, becomes sufficiently thin, it is ruptured. At low volume fraction of one phase, one phase usually consists of disperse drops or bubbles, but as its volume fraction increases the interface structures changes from to more complex irregular shapes, where each fluid is often highly interconnected. Here the focus is on flows where the volume fractions are comparable. The evolution of various integral quantities, such as the average flow rate, wall-shear, and interface area and structure are monitored and compared for different governing parameters such as void fraction and Weber number. Various averages of the flow field and the phase distribution, over planes parallel to the walls, are examined and compared, and the microstructure is examined using two-point correlation functions and other measures.

Monday, November 25, 2019 8:00AM - 10:23AM — Session H04 Granular Flows I 203 - Alban Sauret, University of California Santa Barbara

8:00AM H04.00001 Localized rotational effects on granular temperature. JONATHAN HIGHLAND, University of Liverpool, AVINASH VAIDHEESWARAN, WILLIAM FULLMER, NETL, JONAS SAFFON, Polytech Nantes — The granular temperature of a granular flow is seen to be analogous to a the Reynolds stress inside of a fluid flow. In both cases they represent how energy / momentum is passed around the medium. The main difference between a fluid flow and a granular flow is fluid flows physics is governed by its viscosity, whilst a granular flow is governed by collisions and surface roughness. In a recent paper by Higham et al. (2019) it was shown a combination of individual surface roughnesses and collisions can cause rotational moments to be passed between the individual grains. These three dimensional rotations are not typically taken into consideration in simulations or in experiments, but can have quite an effect on the individual energy / momentum fluxes. In this presentation we present an experimental investigation of a two-dimension driven vortex in a granular flow. We use particle tracking to determine the spatial and rotational translations. From these data we determine what effect the localized rotations have of the granular temperature.
8:13AM H04.00002 A Depth-Averaged Method for Estimating Velocity Profile Evolution in a Granular Flow1. BENJAMIN YOUNG, STUART DALZIEL, NATHALIE VRIEND, University of Cambridge — We present a method for estimating the depth-dependent velocity profiles of free surface granular flows from evolving surface velocity and flow-depth data. We first derive a quasi-two-dimensional three-variable depth-averaged model for free surface flows that accommodates the inclusion of a varying basal boundary condition. This model is then used in conjunction with an ensemble Kalman Filter (enKF) and free surface data to examine the inverse problem: What is the internal velocity field of the flow, given our model and free surface data?. We demonstrate the capabilities of this method by applying our algorithm to the Blasius boundary-layer problem described in Tsang et al. (2018). Synthetic, evolving free surface data is generated from discrete particle model (DPM) simulations and then input into the enKF/depth-averaged algorithm in order to estimate the internal velocity. These estimates are then compared to the coarse-grained DPM velocity field and are shown to provide a good fit to the synthetic data. We believe our method has clear potential, not just in modelling free surface flows, but also as a powerful data-analysis tool for experimentally validating modelling work done within the granular community.

8:26AM H04.00003 Using directional-specific shear rates to correlate mass flow rate and velocity profiles in a granular conveyor1. NICHOLAS POHLMAN, HANNAH HIGGINS, MICHAEL ROEING-DONNA, JIFU TAN, Northern Illinois University — Velocity profiles and total mass flow rate of an industrial-style conveyor system with a storage hopper is explored using both experiments and simulation. Despite expectations of quasi-two-dimensional behavior, the velocity profiles observed at the side walls are not consistent throughout the stored material above the flighted conveyor belt. Integrating velocity profiles from high speed imaging of the experiment proved to underestimate the total mass flow rate of the system when different opening sizes and belt speeds were used. Simulations using the LIGGGHTS platform with boundary conditions similar to the experimental parameters confirm that velocity adjacent to the flights may be constant but non-uniform due to the jam-prevention gaps between flights and the walls. Results indicate that the shear rate decays differently in gravitational versus transverse directions. Fitting parameters for two unique shear rates were applied to allow better correlation of the velocity profiles and mass flow rates that were measured.

8:39AM H04.00004 Slow granular flows in a Split-Bottom Couette device. PETER DSOUZA, PRABHU NOTT, Indian Institute of Science — We present DEM simulations and experiments of slow shear of granular materials in a split-bottom Couette device. This device is a cylindrical cup with a split base, wherein a central disc that is flush with the bottom rotates, while all other walls of the device are stationary¹. Shear originates at the split between this disc and the rest of the base. This device has been widely used to validate rheological models for granular flows since it exhibits wide shear bands. We show that by changing the fill height of the device, we change the location of shear in the material. We then show the presence of system spanning vortices in addition to the primary azimuthal flow. These vortices are like those seen in the cylindrical Couette device². We show that the form of the vortices can be explained by accounting for shear-induced dilation in the system, validating the arguments made for the vortices seen in the Cylindrical Couette device². No current rheological models for slow granular flow allow for shear-induced dilation and thus can’t capture these vortices. We thus make the case that dilation needs to be included in any rheological model for slow granular flows. 1. Dijksman, & van Hecke, 2010, Soft Matter 2. Krishnaraj, & Nott, 2016, Nature Comm

8:52AM H04.00005 Experimental study of the collapse of cohesion-controlled granular materials1. ALBAN SAURET, UC Santa Barbara, ADRIEN GANS, IUSTI, Aix Marseille Univ, CNRS, MINGZE GONG, UC Santa Barbara, OLIVIER POULIQUEN, MAXIME NICOLAS, IUSTI, Aix Marseille Univ, CNRS — Cohesive granular media are encountered in many geophysical and industrial applications, examples being cement, pharmaceutical powders, or flours. Many progress has been made in the description of dry granular flow, but the flow behavior of powders remains elusive. In particular, one difficulty lies in the cohesion force between the particles. Using a recently developed method to create a Cohesion Controlled Granular Material (CCGM) and relate the interparticle cohesion to the macroscopic behavior, we consider experimentally the collapse of a column made of cohesive grains. This configuration has been extensively studied in the case of dry granular material: when the grains are released, the granular mass spreads and stops at a finite distance. The morphology of the deposit is mainly controlled by the initial aspect ratio and is independent of the material properties. Yet, for powders the inter-particle forces strongly affect the collapse. Here, we characterize the effects of cohesion on the collapse dynamics, the run-out length, and the final morphology of the deposit. These experiments illustrate that cohesive forces between particles introduced an additional complexity in this system.

9:05AM H04.00006 Energy evolution in the subaqueous granular column collapse process. YI AN, WENTAO ZHANG, Institute of Mechanics, Chinese Academy of Sciences, QINGQUAN LIU, Beijing Institute of Technology — We studied the energy evolution in the subaqueous granular column collapse process experimentally in this work to understand the unusual phenomena of long-runout reported by V. Topin et al. (PRL, 2012). We set up a well-controlled experimental facility with only one granular width to study the one layer subaqueous granular column collapse problem. We obtained the velocity field for both granular and liquid simultaneously by employing the refractive index matching and planar laser-induced fluorescence. We use Hough transform to identify and track the spherical granular and the 2D Particle Image Velocimetry to obtain the velocity field outside the granular body. We find the total kinetic energy $E_k$ of the granular materials drop dramatically when granular particles turn horizontal with a sharp angle, which implies the granular collision is the key factor determining the runout. The viscosity of the ambient liquid may play multiple roles, on one hand, it reduces the total local collision events, on the other hand, it not only dissipates the kinematic energy but also extends the duration of the entire event. Thus a non-dimensional number describing the role of the viscosity is suggested.

9:31AM H04.00008 Bed-load characteristics over evolving and developed subaqueous barchan dunes1, ERICK M. FRANKLIN, CARLOS A. ALVAREZ, UNICAMP - University of Campinas — In the morphodynamics of crescent-shaped dunes, known as barchans, many complex aspects are involved. One of them concerns the trajectories of individual grains over the dune, and how they affect its shape. In this study, we investigate experimentally the formation and evolution of subaqueous barchan dunes in a closed conduit. In our experiments, granular heaps of conical shape were placed on the bottom wall of a rectangular channel and they were entrained by turbulent water flows. We measured the trajectories of grains migrating to horns of both evolving and developed dunes and showed that most of the grains came from peripheral regions upstream of the dune centroid, with significant transverse displacements. These results diverge from the generally accepted description that the barchan horns form from the advance of the lateral dune flanks. Hence, our results reveal a new mechanism for barchan formation that might be complementary to that accepted so far.

Franklin is grateful to FAPESP (Grants No. 2016/13474-9 and No. 2018/14981-7), to CNPq (Grant No. 400284/2016-2) and to FAPEPE/UNICAMP (Grants No. 2210/18 and No. 2112/19) for the financial support provided.

9:44AM H04.00009 Unsteady Shearing of a Granular Material in an Anular Couette Cell1, HAN-HSIN LIN, MELANY HUNT, California Institute of Technology — We study the transition from unsteady to steady state shearing of spherical glass beads and irregular sands in a Couette cell. By initially fluidizing the bed or compressing with a constant force, we ensure the initial state is controlled and repeatable. By comparing to simulations, we are able to capture the structure change inside the bulk. When controlling the torque, the system cannot reach a steady state when it is below a critical stress. When controlling the speed of the boundary, the shear stress at the wall increases slowly over a period of time that depends on the initial state of the bed, wall friction, shear rate, and flow along the free surface. At steady state, the stress decreases at the highest rotation speeds. Simulations with LAMMPS using Hooke's contact model show a recirculation cell driven by gravity and the free surface, which results in the increasing stress observed in the measurements. The relations of wall friction angle to normal stress for different samples have different trends. The effective friction of the inner wall matters. When using the smooth cylinder, the system needs more time to reach a steady state than using the rough cylinder. At steady state, the wall stress decreases more significantly at the highest rotation speeds compared to the rough cylinder.

9:57AM H04.00010 Wiggling arthropods induce flow in granular materials1, KAREN DANIELS, MELIA KENDALL, SHIH-YUAN CHEN, EMILY BROWN, BJORN SUMNER, MICHAEL MANN, North Carolina State University — Just as heating a viscous fluid causes its viscosity to drop, we observe that the introduction of active particles into a passive granular material can increase its flowability. This effect can be observed, for instance, in the historical practice of aging Milbenkase cheese in mixtures of flour and mites. In our experiments, we examine this effect by introducing flour beetle larvae (Tribolium confusum) into agricultural grains of various sizes. We measure the timescale for bulk flow via the relaxation of a sloping pile, and the timescale for particle-scale rearrangements via diffusing wave spectroscopy. We find that the macroscopic and microscopic timescales are approximately proportional; both timescales decrease as the fraction of larvae increases, but only for samples in which the grains are smaller than the larvae. For samples in which the larvae and grains are of similar size, these two timescales decouple.

1NSF DMR-1608097

10:10AM H04.00011 Experimental measurements of the torque and normal force on a helix rotating in a granular material, ROGELIO VALDEZ, Universidad Nacional Autonoma de Mexico, MELANY HUNT, California Institute of Technology, ROBERTO ZENIT, Brown University — The torque and normal force produced by a helix rotating in granular matter were measured experimentally. The experiments were conducted using the rheometer, with a powder cell, for a wide range of rotational speeds. Two granular media were considered: mustard seeds and glass beads with diameter 0.203 mm. The experiments considered changes in the geometry of the helix. For a first set of tests, seven helices with the same total length but with different helix angle and wavelength were considered. For the second group, ten helices with the same geometric shape but with different numbers of turns, from 1 to 9, were used. The results show that torque and normal force are strongly dependent on the helical geometry. A maximum normal force is reached when the helix angle is around 55 degrees while the peak for the torque occurs when the helix angle is close to 40 degrees. In both cases, the measurements are nearly independent on the rotational speed of the helix. Both force and torque increase linearly with the number of coil turns for small number of coils; however, in contrast to what may be expected for a viscous fluid, the increase is not linear when the number of coils is larger than 3. Comparisons with calculations from granular resistive force theory will be presented.
8:00AM H05.00001 The Effects of Parasitic Combustion on Detonation Wave Propagation¹, SUPRAJ PRAKASH², VENKAT RAMAN³, University of Michigan — Rotating detonation engines (RDEs) are a feasible approach to realizing pressure gain combustion. However, practical implementation of these devices requires the use of non-premixed discrete fuel-oxidizer injection. Turbulent mixing of the fuel and oxidizer streams enforces reactant stratification inside the combustor annulus. Parasitic deflagrative combustion of the freshly-injected fuel-oxidizer mixture introduces partially-burnt gases to the detonation wave and diminishes heat release. Numerical studies of full-scale RDE systems have suggested that up to 35-50% pre-burning of the fuel-oxidizer mixture is prevalent within the combustor. The primary objective of this work is to understand the interaction of the detonation wave and a spatially-inhomogeneous mixture. To this end, a high-fidelity numerical simulation approach is utilized to understand how partially-burnt mixtures affect the detonation wave structure by inducing different fractional levels of reactant mixture pre-burning with reference to the fully-burnt equilibrium state. The effect of pre-burning on detonation wave stability and characteristics are discussed to provide insight into the difference between theoretical Chapman-Jouguet detonation and the detonative combustion observed in practical combustors.

1The research is supported by DOE/NELT University Turbine Systems Research under DOE Grant Nos. DE-FE00025315 and DE-FE00023983.

8:13AM H05.00002 Quantification of Detonation Augmentation by Secondary Waves in a Rotating Detonation Combustor¹, FABIAN CHACON, MIRKO GAMBA, University of Michigan — In this work we will investigate the system of waves present in a laboratory scale rotating detonation combustor (RDC). These devices are of scientific interest because of the theoretical efficiency gain that can be achieved through the utilization of these devices in a jet engine or other conventional combustor. However, the flow fields within RDCs are complex and not fully understood, nor are many of the mechanisms behind some of the phenomena associated with a RDC. One such phenomena is termed secondary waves: waves (apart from detonation) which have some associated pressure oscillation, chemical reactions, or both travelling at a consistent speed while the combustor is under operation. In particular, we will use a newly developed analysis technique that allows for the quantification of spatial distributions of pressure throughout the operation of the RDC. This will allow for determining the impact that the secondary wave has on the pressure rise of the detonation wave when they collide in the channel. Understanding how significant the impact of these collisions are, will allow for greater understanding of the role these secondary waves will play into the operability and stability of a RDC and its integration into a practical system.

1This paper is based on work supported by the DOE/NELT University Turbine Systems Research under DOE Grant No. FE0031228 with Robin Ames as program monitor.

8:26AM H05.00003 Effects of non-premixed injection schemes on the detonation structure in rotating detonation engines¹, TAKUMA SATO, VENKAT RAMAN, University of Michigan — Recently, RDEs has been getting more attention as the pressure gain combustor. Because it uses the detonation in the combustion process, the reactant mixture can get additional compression due to the shock wave. Although a series of simulations have been conducted in the community, most of them are limited in the canonical problems and the premixed assumption in a 2D geometry. In the real RDEs system, the non-premixed injection system creates a complex detonation structure due to the incomplete mixing and the stratification of the fuel and oxidizer. However, the measurement of the detailed flame structure is hard to obtain in the experiment due to the harsh environment of the system. With this mind, the goal of this study is to understand the detailed 3D detonation structure by simulating the full system RDEs system. Because the flow-field is highly unsteady in time and space, the 3D averaged flow-field will be extracted from the simulation. The heat release distribution in the space will be extracted to understand the combustion process in the detonation chamber. The mixing process of the non-premixed injection system will be discussed by varying the mass flow rate. Finally, the comparison between the Euler and Navier-Stokes equations will be discussed.

1DOE-NELT DE-FE00025315, DOE-NELT DE-FE00023983

8:39AM H05.00004 Analysis of mode transition in Rotating Detonation Engines using detailed numerical simulations, PRASHANT TAREY, PRAVEEN RAMAPRABHU, University of North Carolina, Charlotte, JACOB MCFARLAND, University of Missouri, Columbia, DOUGLAS SCHWER, Naval Research Laboratory, Washington DC — Detonation Engines (RDE) can operate in single or multiple detonation wave modes, while the mode of operation depends on several factors including the equivalence ratio, mass flow rate etc. In this work, we analyze the mechanism of mode transition through detailed numerical simulations of a 2D unrolled RDE geometry with discrete injectors. We systematically vary the equivalence ratio of the hydrogen-air mixture in our simulations with 1-step chemistry. The different modes of operation and the parameter boundaries separating them, were investigated and compared with experimental¹ results. Our results show that the number of waves is proportional to the equivalence ratio as well as the detonation cell width. The effect of the detonation modes on thrust and detonation height were also investigated. The compressible Euler simulations were solved on a Cartesian grid with Adaptive Mesh Refinement, using the Piecewise Parabolic Method (FLASH²), while a second-order accurate, Immersed Boundary Method was implemented to model the discrete injectors. ¹A. George et al., Proc. Comb. Inst., 36 (2), 269L. (2017). ²B. Fryxell et al., Astrophys. J., Suppl. Ser. 131, 273 (2000).

8:52AM H05.00005 ABSTRACT WITHDRAWN —

9:05AM H05.00006 Numerical Investigation of the Accuracy of Particle Image Velocimetry Technique in Gas-Phase Detonations, SAI SANDEEP DAMMATI, YORAM KOZAK, Texas A&M University, KAREEM AHMED, University of Central Florida, ALEXEI POLUDNENKO, Texas A&M University — In this study, we numerically investigate the accuracy of the Particle Image Velocimetry (PIV) technique for the flow characterization in high-speed, compressible regimes, and in particular in gas-phase detonations. A two-dimensional, planar detonation at atmospheric conditions is modeled using a simplified single-step Arrhenius kinetics. The upstream flow is uniformly seeded with particles representing the Al2O3 PIV particles used in experiments, along with initially co-located massless Lagrangian tracers used to recover the correct particle trajectories in the flow field. Massless Lagrangian particles are integrated using both 2nd order and 4th order time integrators to further assess the errors in the reconstructed Lagrangian trajectories. By comparing the trajectories of massive particles with those of the tracer particles, we address the following questions: a) How do PIV particles affect the detonation wave, in particular its velocity and cellular structure? b) How closely do massive PIV particles follow the flow pathlines? c) What is the accuracy of the flow field reconstructed using the PIV particles? Finally, we discuss the implications for the use of the PIV technique as a diagnostic tool for high-speed reacting flows such as detonations in detonation-based engines.

¹Department of Defense High Performance Computing Modernization Program
Scramjets with Hydrogen, Methane, and Ethylene Fuels, WENHAI LI, TTC Technologies, Inc., LADEINDE FOLISIO, Department of Mechanical Engineering, Stony Brook University — A few results on flame stability and thermal choking in a simplified model of the scramjet engine will be presented for hydrogen, methane, and ethylene fuels which are injected in crossflow to a supersonic airflow in a combustor. The parameter space investigated includes a range of air stagnation temperatures ($T_0$), jet-to-freestream momentum flux ratios ($J$), and the three fuels. The analysis is done via the large-eddy simulation and within the context of the flamelet approach. Preliminary results show that hydrogen and ethylene have similar thermal choking limits in terms of $T_0$ and $J$, while the methane flames are quite difficult to maintain under the current test conditions.

Modeling of the Cellular Structure of Detonation in Liquid Explosives, LUKE EDWARDS, University of Arizona, MARK SHORT, Los Alamos National Laboratory — Detonation waves propagating in some liquid explosives such as nitromethane (NM) are known to exhibit complex cellular patterns reminiscent of those observed in gaseous explosives. Such cellular structures in NM/diluent mixtures have been recorded by framing camera images (Fickett and Davis 1979). The origins of such instabilities are disputed, ranging from hydrodynamically generated instabilities to failure waves propagating into the detonation reaction zone from the NM/confiner boundary. Detonation front shapes measurements by streak camera imaging in NM/diluent mixtures, on the other hand, mostly show smoothly curved shock fronts, which appear to contradict the observed presence of cellular instabilities. We also know that detonations in NM mixtures are carbon rich, which results in a spatially elongated zone of carbon coagulation behind a much thinner main reaction layer. In this work, we examine the potential origin of the observed cellular detonation instabilities in NM mixtures via an asymptotic theory that explicitly accounts for the long carbon coagulation region. The theory explores why the presence of cellular instabilities may not manifest themselves on the detonation shock front.

Steady Detonation Propagation in Thin Channels with Strong Confinement, MARK SHORT, STEPHEN VOELKEL, CARLOS CHIQUETE, Los Alamos National Laboratory — We examine asymptotically the dynamics of 2D steady detonation wave propagation and failure for a strongly confined high explosive (HE), where the width of the explosive is small relative to the reaction zone length. An energy balance equation is derived which shows how the longitudinal acceleration of subsonic flow behind the detonation shock is influenced both by chemical reaction and by the effects of HE boundary streamline deflection, specifically via the induced rate of change of mass flux through the detonation wave. The latter serves to either counteract or reinforce the acceleration of longitudinal flow depending on the gradient of the boundary streamline deflection. The analysis is valid for general equations-of-state and chemical reaction rates in the HE. The energy equation represents an eigenvalue problem for the detonation phase speed. We explore specific results for the ideal- and stiffened-gas equations of state, along with a pressure-dependent reaction rate for which changes in the pressure exponent and reaction order are also studied. We consider the influences of both straight and curved HE boundary streamline shapes. The asymptotic analysis reveals significant physical insights into how detonation propagation and failure is affected by strong confinement.

The effect of the thermodynamic closure on shock-to-detonation transition modeling in condensed-phase high explosives, CARLOS CHIQUETE, MARK SHORT, STEPHEN VOELKEL, Los Alamos National Laboratory — The need for accurate prediction of detonation initiation and propagation in high explosives (HEs) has lead to various empirical constitutive models for the HE’s equation of state (EoS) and reaction rate. These experimentally calibrated models are used at the continuum level where it is possible to efficiently calculate detonation wave motion at the engineering scale. A transition from the (solid) reactant to the (gas) product state occurs via a single irreversible reaction, requiring a closure condition between the two phases which must then coexist in a single material element. Different closures have been used in the past, for example, pressure-temperature equilibrium. However, analysis of more physical, explicitly 2-phase modeling approaches where each phase’s thermodynamic state can evolve from the (solid) reactant to the (gas) product state occurs via a single irreversible reaction, requiring a closure condition between the two phases which must then coexist in a single material element. Different closures have been used in the past, for example, pressure-temperature equilibrium. However, analysis of more physical, explicitly 2-phase modeling approaches where each phase’s thermodynamic state can evolve have shown that temperature equilibration occurs over a much longer time scale than the corresponding reaction zone scale. Nevertheless, this “nonphysical” closure has been shown to capture the shock-to-detonation-transition (SDT) for many HEs. To clarify this, we systematically vary the closure condition and isolate its effect by fixing the EoS models and reaction rate form. Computational results using the various closures will then be compared and contrasted with respect to SDT data.

Analysis of Detonation Driving Zone in Condensed-Phase High Explosives at Varied Confinements, STEPHEN VOELKEL, CARLOS CHIQUETE, MARK SHORT, Los Alamos National Laboratory — Lateral yielding of confiners used in detonations of condensed-phase high explosives (HEs) introduces streamline divergence into the flow and subsequently reduces the detonation’s phase velocity to below its planar Chapman-Jouguet (CJ) limit. The resulting phase velocity is determined by the subsonic flow region behind the shock front, denoted the detonation driving zone (DDZ). The DDZ itself is dependent on the HE material properties, the thickness of the charge, and the confiner properties. Holding all else equal, at infinite thickness the phase velocity approaches the CJ limit. As the thickness decreases, so does the phase velocity until the thickness reaches some critical value, below which the detonation is unable to sustain itself. In this work, we consider an idealized HE material and simulate steady detonations over a wide range of confinements. For each confinement, simulations at varied thicknesses between the CJ and critical limits are performed and analyzed. Correlations of the DDZ with the phase velocity are presented, with a specific focus on structures and relations that are independent of the confinement. Furthermore, we show that properties within the DDZ correlate with the critical thickness.

Monday, November 25, 2019 8:00AM - 10:36AM – Session H06 Reacting Flow Instabilities and Near-Limit Flames 205 - Carlos Pantano, University of Southern California
8:00AM H06.00001 A Computational Study on Chemical Characteristics of Bluff-body-stabilized Lean Premixed Flames1. YU JEONG KIM, WONSIK SONG, FRANCISCO E. HERNANDEZ PREZ, King Abdullah University of Science and Technology (KAUST), BOK JIH LEE, Seoul National University, HONG G. IM, King Abdullah University of Science and Technology (KAUST), KAUST TEAM — Bluff-body flame holders have been used to achieve stable combustion by recirculating hot product gases behind the holders in premixed reacting flow systems under highly unstable conditions. Despite assisting to improve combustion stability, holders also induce instabilities to flames and flow fields such as vortex shedding and blow-off. In the present study, high-fidelity direct numerical simulations are conducted to investigate flame dynamics behind a bluff-body in lean premixed mixtures and to understand the flame stabilization mechanism, in particular under hydrodynamic instabilities. A three-dimensional rectangular channel with a square-section bluff-body flame holder is selected as configuration. Several distinct flame instabilities are identified as the blow-off limit is approached. The sequence of key physical mechanisms, such as extinction and re-ignition, and combustion and chemical characteristics of the flames are also examined using the combined approach of computational singular perturbation and tangential stretching rate.

8:13AM H06.00002 Effect of compressibility on laminar flame speed and its influence on the Darrieus-Landau instability of a planar front of premixed flame1. YASUHIDE FUKUMOTO, Institute of Mathematics for Industry, Kyushu University, KEIGO WADA, Center of Coevolutionary Research for Sustainable Communities, Kyushu University, SNEZHANA ABARZHI, The University of Western Australia — The effect of compressibility on a premixed flame front is investigated by use of the method of $M^2$ expansions for small Mach numbers. We study the inner structure of the reaction layer, by applying the method of matched asymptotic expansions to an overall one-step irreversible chemical reaction expressed by the Arrhenius law. We figure out the structure of freely propagating deflagration wave from the perspective of the temperature distribution and the laminar flame speed. The temperature distribution is greatly influenced by the compressibility effect which originates from the material derivative of the pressure in the source term of the heat-conduction equation. This effect sensitively drops down by the compressibility effect. This implies that the compressibility acts to reduce the growth rate of the Darrieus-Landau instability.

8:26AM H06.00003 Gravity effects on the nonlinear dynamics of premixed flames. CHRISTOPHE ALMARCHA, BASILE RADISSÖN, BRUNO DENET, Aix Marseille Université, CNRS, Centrale Marseille, IRPHE UMR 7342, 13384 Marseille, France — During their propagation, premixed flames are unstable and undergo a rich dynamics that can be favorably compared to the integration of Michelson-Sivashinsky (MS) equation. Three main ingredients are involved in this nonlinear partial differential equation: the Darrieus-Landau non-local instability, the normal propagation of the front and a small scale diffusive stabilization. In order to take into consideration the long range effects of gravity, we study a modified (MS) equation where a linear stabilizing term is added. We demonstrate that this modified equation is capable of reproducing features of experimental 2D flames propagating downwards in a Hele-Shaw burner. In particular, although the additional term is linearly stabilizing, it is responsible for an increase in the fragmentation of the interface into smaller cells.

8:39AM H06.00004 Nonlinear stability of a premixed flame subjected to a transverse shear2. XIAOYI LU, MOSHE MATALON, University of Illinois at Urbana Champaign, CARLOS PANTANO, University of Southern California — We present our findings on the hydrodynamic stability behavior of a premixed flame subjected to a transverse shear. The analysis is carried out in the weak thermal expansion limit resulting in a modified Michelson-Sivashinsky (MS) equation, which describes the evolution of the flame surface. Numerical solutions to the MS equation show that due to the transverse shear, the flame develops a skewed cusp-like flame, that steadily propagates into the unburned gases and simultaneously translates along the transverse direction. Both propagation and translation velocities are shear-dependent. The fully nonlinear evolution of premixed flames with a realistic density jump at higher shear levels is then investigated using the Direct Numerical Simulations approach.

8:52AM H06.00005 Flow Field Measurements for Instability Mitigation in Lean Direct Injection3. JOSHUA KRSEK, Rose-Hulman Institute of Technology — Lean direct injection (LDI) is a method of combustion used in aviation gas turbines which results in reduced emission of carbon monoxide, nitric oxides (NOx), soot, and unburned hydrocarbons. LDI often results in potentially destructive thermoacoustic instabilities, which can lead to combustor structural failure. A ceramic foam insert has been shown to passively mitigate such thermoacoustic instabilities. Further work has shown that this effect is caused at least in part by the porosity of the insert, as fully dense inserts are not universally effective at mitigating these instabilities. This study attempts to develop a fundamental understanding of the combustor flow structure by analyzing particle image velocimetry (PIV) for combustion under the presence of a porous insert, solid insert, and no insert. The results from this study will play a pivotal role in the design of an optimal instability-weakening porous insert for the NASA developed swirler-venturi injector.

9:05AM H06.00006 Acoustically-Coupled Combustion Dynamics of Laminar Microjet Diffusion Flames4. ANDRES VARGAS, JOSE GUERRERO, ANN KARAGOZIAN, HYUNG SUB SIM2, University of California, Los Angeles — The present experiments focus on the response of burning gaseous fuel jets to prescribed transverse acoustic excitation as a means of exploring the coupling of reactive, acoustic, and flow processes relevant to combustion instabilities. Microjets with several alternative configurations and sizes (including single and multiple jets) and different fuels are exposed to transverse standing wave disturbances within an acoustic waveguide for which a range of resonant frequencies and amplitudes of excitation are applied. Temporal flame response to acoustic excitation is studied via OH* chemiluminescence and visible imaging, with quantification of the dynamics via proper orthogonal decomposition (POD), Rayleigh indices, and temporal flame distortion measurements. Characteristic signatures associated with various types of flame response are identified, including weakly oscillatory combustion, full-scale flame lock-in to excitation, and multi-mode flame dynamics preceding flame extinction. Phase space plots of dominant POD mode coefficients produce periodic as well as strange attractor-like shapes for high amplitude forcing.

9:18AM H06.00007 Theoretical Source Statistics of Thermo-Acoustic Instability within Reacting Flow. STEVEN MILLER, University of Florida, Department of Mechanical and Aerospace Engineering. We develop a statistical tool based on the equations of motion to quantify the various acoustic sources that cause thermo-acoustic instability. The Navier-Stokes equations, energy equation, and mass fraction equations are decomposed into their base, aerodynamic, and acoustic components. The acoustic components are solved for via the method of the vector Green’s function. The spectral densities of acoustic fluctuations are then formed. The resultant two-point cross-correlations of the Navier-Stokes operator, energy equation operator, and mass fraction operator on the resolved aerodynamic flow-field yield thermo-acoustic statistical sources. Resultant sources are the two-point cross-correlations consisting of terms involving traditional aerodynamic interactions, aerodynamic-combustion interactions, and combustion-combustion interactions. We show that under certain simplifying assumptions, the traditional Rayleigh criterion and combustion acoustic equations are recoverable. We compare the newly proposed theory to traditional Rayleigh criterion and acoustic equations. The benefit of the theory is all thermo-acoustic sources are accounted for in a single two-point cross-correlation model, which is consistent with traditionally accepted theory.

9:31AM H06.00008 Computational Investigation of Combustion Instability in a Gas Turbine Model Combustor. NICHOLAS ARNOLD-MEDABALIMI, CHENG HUANG, KARTHIK DURAISAMY, University of Michigan. Gas combustion is expected to see continued use in propulsion and energy applications for the foreseeable future. Lean operating conditions are desired from an emissions standpoint but can lead to thermoacoustic instabilities. Gas Turbine Model Combustors (GTMC) have been investigated in recent years to improve our understanding of the underlying phenomena. A well-examined experimental design is that of Meier et al. investigated both at DLR and the University of Michigan. In this work, we perform reacting Large Eddy Simulations (LES) of this partially premixed swirl stabilized burner at various operating conditions with particular interest in thermoacoustically unstable regimes. Detailed validations are presented with experiments, and time-averaged field characteristics, acoustics, and coherent structures are examined. The impact of turbulent combustion closure models is examined by comparing the performance of finite-rate chemistry and flamelet regimes. Detailed validations are presented with experiments, and time-averaged field characteristics, acoustics, and coherent structures are examined. The impact of turbulent combustion closure models is examined by comparing the performance of finite-rate chemistry and flamelet regimes.

9:44AM H06.00009 Temporal linear stability analysis of laminar flames on inclined fuel surfaces. RAQUEL HAKES, University of Maryland, WILFRIED COENEN, ANTONIO SANCHEZ, University of California, San Diego, MICHAEL GOLLNER, University of Maryland, FORMAN WILLIAMS, University of California, San Diego. Experiments have found substantial structural differences between buoyancy-driven flames developing on the upper and lower surfaces of inclined burning plates. These differences cannot be explained with existing analytical solutions of steady semi-infinite flames, which provide identical descriptions for the top and bottom configurations. We perform a temporal linear stability analysis to investigate the potential role of flame instabilities in the experimentally observed flow differences. The problem is formulated in the limit of infinitely fast reaction, considering the non-unity Lewis number of the fuel vapor. The analysis incorporates nonparallel effects of the base flow and considers separately spanwise traveling waves and Görtler-like streamwise vortices. The solution to the stability problem determines the downstream location at which the flow becomes unstable, characterized by a critical value of the local Grashof number, which varies with the plate inclination angle. The results for the underside flame indicate that instabilities emerge further downstream than they do for a topside, in agreement with experimental observations. Increased baroclinic vorticity production is reasoned to be responsible for the augmented instability tendency of topside flames.

9:57AM H06.00010 Near-limit H₂-O₂-N₂ combustion in nonpremixed counterflow mixing layers. PRABAKARAN RAJAMANICKAM, University of California San Diego, JAIME CARPIO, Universidad Politecnica de Madrid, ANTONIO L. SANCHEZ, University of California San Diego, PAUL D. RONNEY, University of Southern California, FORMAN A. WILLIAMS, University of California San Diego. Numerical computations employing detailed chemistry and experiments in a slot-jet counterflow burner are used to characterize the different combustion modes emerging in mixing layers separating N₂-diluted counterflowing planar streams of hydrogen and oxygen. Attention is focused on high degrees of dilution resulting in near-critical flames with peak temperatures close to the crossover temperature. A bifurcation diagram is presented in the mixture-fraction vs. strain-rate plane that identifies six different combustion regimes involving four different flame types, namely, diffusion-flame sheets, propagating RETREATING edge flames, broken-flame tubes, and isolated flame tubes. While the isolated flame tube is always stationary, the broken flame tubes can be stationary or can propagate with an oscillatory speed. The observed flame behavior exhibits hysteresis in some parametric regions, where the flow that is established depends on the ignition mechanism.

10:10AM H06.00011 Quantification of local combustion modes in laminar non-premixed n-dodecane/air coflow flames. CHAO XU, SIBENDU SOM, Argonne National Laboratory. Non-premixed lifted jet flames in heated air coflow are important to a range of practical propulsion systems, while stabilization mechanisms for complex fuels have not been fully understood. To better understand the structure and stabilization mechanisms, two-dimensional laminar n-dodecane jet flames in heated air coflow at 30 atm are simulated with detailed chemical kinetics. To quantify roles of different sub-processes (e.g., chemistry, diffusion, radiation, etc.) and associated local combustion modes, a new flame diagnostic based on chemical explosive mode (CEMA) analysis is developed, by projecting local chemical and diffusion source terms to the direction of CEM and quantifying the competition between these terms. Diffusion processes in both normal and tangential directions of the non-premixed flame sheet (defined as the mixture fraction isocontours) are further accounted for. Additional local combustion modes specific to nonpremixed flames (compared to premixed flames) are identified, highlighting different roles of flame-normal and flame-aligned diffusion processes in stabilizing the flames. Effects of radiative loss on local combustion modes and the flame stabilization mechanism, are also discussed based on an optically-thin radiation model.

10:23AM H06.00012 Numerical study on the stabilization of ball-like reacting fronts at normal gravity. FRANCISCO HERNANDEZ PEREZ, King Abdullah University of Science and Technology, ZHEN ZHOU, YURIY SHOSHIN, JEROEN VAN OIJEN, PHILIP DE GOEY, Eindhoven University of Technology, HONG IM, King Abdullah University of Science and Technology. A computational investigation on the stabilization and dynamics of lean premixed flames in tubes at near lean-limit conditions is conducted. Hydrogen-methane-air premixed mixtures are considered in tubes with two different diameters (13.5 and 55 mm) and under the influence of normal gravity. As the lean flammability limit is approached, individual (13.5 mm tube) and multiple (55 mm) ball-like flames are formed and stabilized. Through high-fidelity simulations with detailed transport and chemical models as well as the inclusion of heat losses, the stabilization and dynamics of such flames are examined.

8:00AM H07.00001 On particle distribution in High-Order Smoothed Particle Hydrodynamics schemes, RENATO VACONDIO, university of parma — Smoothed particle hydrodynamics (SPH) numerical schemes are becoming very popular in CFD due to their Lagrangian and meshless nature. Nevertheless, many arising numerical issues still remain to be investigated. One of the major drawbacks of such meshless schemes is the low order convergence rate due to particle spatial anisotropy. To overcome this, considerable work has been done towards introducing kernel corrections. Nevertheless, these might lead to instabilities and break the conservation properties of the numerical scheme. Recently, it was demonstrated that schemes such as diffusion-based particle shifting are able to improve the accuracy of the approximations however, they do not conserve linear and angular momentum. In the present work, an arbitrary Lagrangian-Eulerian scheme (ALE-SPH) has been developed where the transport velocity is computed by means of an iterative particle shifting scheme which ensures a near isotropic particle distribution spatially. Moreover, a new class of kernels have been adopted that can guarantee an arbitrary order of convergence (at the continuous level of spatial interpolation). In this way, we have been able to attain the theoretical order of convergence of the adopted kernel (for example 4th or 6th order) preserving the conservation properties.

8:13AM H07.00002 Modeling Astrophysical Transients with Smooth Particle Hydrodynamics, CHRIS FRYER, Los Alamos National Laboratory — Mesh free methods, and smooth particle hydrodynamics in particular, have been used extensively in modeling astrophysical transients. The ability of SPH to conserve angular momentum, easily include detailed microphysics, and to resolve the mass over large distance scales makes it an ideal method for many problems. I will present an overview of the wide variety of astrophysical transients modeled with smooth particle hydrodynamics, including supernovae, gamma-ray bursts and merging neutron stars. I will focus on the specific strengths and current issues using these methods to model these problems.

8:26AM H07.00003 Incompressible SPH and New Developments, STEVEN LIND, University of Manchester, SPH@MANCHESTER TEAM — SPH shows considerable promise for modelling a range of challenging fluid phenomena, especially those involving highly deforming free-surface flows or interfaces with potential topology change. SPH is often applied in weakly compressible form, but incompressible SPH is a newer alternative gaining popularity given its ability to predict accurate pressure fields without the use of empirical equations of state, artificial sound speeds, or excessive numerical diffusion. This talk will provide an overview of recent developments for the incompressible SPH approach, including examples of its application in quite diverse areas of fluid mechanics. New methodologies for achieving stability and very high accuracy will also be discussed.

8:39AM H07.00004 A spatially adaptive high-order meshless method for fluid-structure interactions, WENXIAO PAN, WEI HU, University of Wisconsin-Madison, NATHANIEL TRASK, Sandia National Laboratories — We present a scheme implementing an a posteriori refinement strategy in the context of a high-order meshless method for problems involving point singularities and fluid-solid interfaces. The generalized moving least squares (GMLS) discretization used in this work has been previously demonstrated to provide high-order compatible discretization of the Stokes and Darcy problems, offering a high-fidelity simulation tool for problems with moving boundaries. The meshless nature of the discretization is particularly attractive for adaptive h-refinement, especially when resolving the near-field aspects of variables and point singularities governing lubrication effects in fluid-structure interactions. We demonstrate that the resulting spatially adaptive GMLS method is able to achieve optimal convergence in the presence of singularities for both the div-grad and Stokes problems. Further, we present a series of simulations for flows of colloid suspensions, in which the refinement strategy efficiently achieved highly accurate solutions, particularly for colloids with complex geometries.

8:52AM H07.00005 Projection Particle Methods - Latest Advances and Future Perspectives, ABBAS KHAYYER, Associate Professor, Kyoto University, Japan — This talk comprises of a review on the latest achievements made in the context of projection particle methods. Projection particle methods, including Incompressible Smoothed Particle Hydrodynamics (ISPH) and Moving Particle Semi-implicit (MPS), are founded on Helmholtz-Leray decomposition and its corresponding Chorin’s projection method. In this talk this important mathematical concept and related mathematical conditions will be reviewed and its application for ISPH and MPS will be concisely described. Followed by providing the mathematical background, the ISPH and MPS numerical methods will be briefly introduced. The latest achievements corresponding to stability, accuracy and energy conservation enhancements as well as advancements related to simulations of multi-phase flows and hydroelastic fluid-structure interactions will be discussed. In specific, more attention will be dedicated to hydroelastic fluid-structure interactions in the context of projection particle methods, introducing methods for interactions of incompressible fluid flows with elastic structures in both Newtonian and Hamiltonian frameworks. Finally, the future perspectives for further enhancements of applicability and reliability of particle methods will be highlighted.

9:05AM H07.00006 Multiscale SPH model for multiphase flow, AMANDA HOWARD, Pacific Northwest National Laboratory — We present nonlocal multiscale partial differential equations for multiphase flow and their smoothed particle hydrodynamics (SPH) discretization. We demonstrate that this model is able to describe multiphase flow at scales ranging from micro (nano) to macro scales and predicts curvature dependence of the surface tension. The nonlocal model is obtained in the form of an integral of a molecular-force-like function added into the momentum conservation equation. Our SPH simulations of multiphase flow in porous materials and droplet and film flow on rough surfaces further reveal multiscale features of the proposed model.

9:31AM H07.00008 Hydrodynamic Study of an Extraterrestrial Ship Design with SPH

We report results and lessons learned from a study in which three Smoothed Particle Hydrodynamics (SPH)-methods were used for the solution of several fluid-solid Interaction problems. The first SPH approach considered is widely used in the community and it relies on an equation of state to weakly enforce compressibility (called WCSSP, from Weakly Compressible SPH). The second SPH approach uses an implicit solution in which the incompressibility is enforced by a pressure distribution computed via a Poisson equation (called ISPH, from Implicit SPH). Lastly, a constraint-based method is considered that enforces incompressibility by imposing the constant density condition via a kinematic holonomic constraint on the motion of the SPH markers (called KCSPH, from Kinematically Constrained SPH). WCSSP, ISPH and KCSPH are compared in conjunction with five tests: an incompressibility benchmark test, Poiseuille flow, flow around cylinder, dam break, and fluid sloshing. The interest is in comparing solution attributes such as accuracy, robustness, efficiency, and ease of use and implementation. Ultimately, this effort provided a mechanism to probe the agency of the SPH method.

9:44AM H07.00009 A comparison of three SPH methods for the solution of the Fluid-Solid Interaction problem

A thank you to CONACYT for the financial support for this work.

9:57AM H07.00010 GPUSPH modeling of waves and currents in the nearshore

One billion particles and beyond. In these cases, one can contemplate switching to continuum models for granular dynamics. Inspired by the fluid-like behavior of granular material, in this contribution we report on an approach in which granular material dynamics is approximated via a drodynamics scheme. For the fluid flow, we employ the Smoothed Particle Hydrodynamics (SPH) to solve the Navier-Stokes equations. Similarities between the discrete, fully resolved model and the continuum granular material model are reported drawing on a set of three examples: compressibility test, the classical dam break problem, and the dam break simulation with an obstacle.

10:10AM H07.00011 Granular dynamics vs. fluid dynamics: similarities and differences

As shown by Dalrymple and Iribarren (JGR, 1975), synoptic scale wind waves lead to the formation of nodal and anti-nodal lines in the water surface by superposition. This leads to the formation of circulation cells in the nearshore with rip currents flowing offshore on the nodal lines. However, this is only true for small amplitude waves as nonlinear amplitude diffraction leads to waves crossing the linear nodal lines. This leads to isolated wave crests (Wei et al., 2017) and an increase in the number of waves in the surf zone. This nonlinear effect leads to additional circulation cells within the surf zone. We also examine the magnitude of each term in the wave-averaged equation of motion spatially.

10:23AM H07.00012 Numerical simulation of the fluid-structure interaction in an airship through the SPH methodology

The Lagrangian methodology is used to study the stability of the Rolling, Pitching and Yawing moments, and the drag and lift average aerodynamic coefficients. It is assumed that the airship is flying in a low Reynolds number regime in a quasi-compressible medium (air). The numerical results are compared with previous studies, both experimental and numerical simulations using the traditional Eulerian-mesh based methods.

1 A thank you to CONACYT for the financial support for this work
8:00AM H08.00001 Indentation into a plastic fluid layer, THOMASINA BALL, NEIL BALMOUTH, University of British Columbia, IAN HEWITT, University of Oxford — We study the indentation of a rigid object into a layer of a cohesive or non-cohesive plastic material. Existing approaches to this problem using slip-line theory assume that the penetration depth is relatively small, employing perturbation theory about a flat surface. Here, we use two alternative approaches to account for large penetration depths, and for the consequent spreading and uplift of the surrounding material. For a viscoplastic fluid, which reduces to an ideal plastic under the limit of vanishing viscosity, we adopt a viscoplastic version of lubrication theory. For a Mohr-Coulomb material, we adopt an extension of slip-line theory between two parallel plates to account for arbitrary indenter shapes. We compare the theoretical predictions of penetration and spreading with experiments in which a flat plate, circular cylinder or sphere are indented into layers of Carbopol or glass spheres with successively higher loads. There is a clear layer-depth dependence of the indentation and uplift for the viscoplastic material, with a much weaker dependence on layer depth for a Mohr-Coulomb material. Understanding the dynamics of indentation into a viscoplastic layer is of particular importance in the formation of footprints, either by animals or in an industrial process.

8:13AM H08.00002 Dynamics of viscoelastic ribbons, NEIL BAMFORTH, University of British Columbia, IAN HEWITT, Oxford University — A reduced model is presented for the dynamics of slender ribbons of viscoelastic fluid. The model is used to explore the effects of viscoelasticity on the dynamics of a curling ribbon, a drooping cantilever, buckling sheets, snap-through and a falling catenary.

8:26AM H08.00003 Jeffery orbits in shear-thinning fluids, ARMAN ABDIH, GWYN ELFRING, University of British Columbia — At zero Reynolds number, spheroids and long slender bodies in shear flow undergo a periodic motion. In the absence of inertial and Brownian forces, the motion of a neutrally buoyant ellipsoid of revolution in a simple uniform shear was solved by Jeffery who found that the particles axis of revolution rotates on infinitely many degenerate periodic orbits called “Jeffery orbits”. Since this classical work, a number of various studies have demonstrated that inertia (both of the particle and the fluid) and viscoelasticity tend to have a dramatic effect on the particle dynamics, but the effects of shear-dependent viscosity has not previously been explored. In this talk we consider the dynamics of a neutrally-buoyant prolate spheroid in a shear flow of a shear-thinning fluid. We model the fluid using a Carreau model and use perturbation theory about a flat surface. Here, we use two alternative approaches to account for large penetration depths, and for the rheological properties of the shear-thinning liquid and the characteristics of the impacting object. We find that the symmetry of the Jeffery orbits in Newtonian fluids is maintained when the fluid displays shear-thinning, however the changes in viscosity tend to increase the time the particle spends aligned with the flow.

8:39AM H08.00004 Numerical Study of the Flow of a Shear-Thinning Fluid Past a Circular Cylinder Forced to Oscillate Sinusoidally1, UMANG PATEL, JONATHAN ROTHSTEIN, YAHYA MODARRES-SADEGHI, University of Massachusetts Amherst — Current study numerically investigates two-dimensional laminar flow of shear-thinning fluids past a circular cylinder forced to oscillate in crossflow direction. Merged PISO-SIMPLE algorithm (PIMPLE) has been used to solve the governing equations on unstructured grid. The sinusoidal oscillations of cylinder were handled by solving cell-centre laplacian for mesh motion displacement. Oscillation frequency has been kept in such a way that a reduced velocity remains close to 6. The shear-dependent viscosity has been modelled by the Carreau model where power index is kept below unity to model shear thinning fluid. Reynolds number is defined based on zero shear-rate viscosity. Vortex shedding is observed at very low Reynolds number as compared with the Newtonian fluid since shear-thinning effects are causing the flow to destabilize. For various values of Reynolds number and Carreau model parameters, lift and drag coefficients as well as time- averaged normalized viscosity have been reported. As opposed to Newtonian fluids, we observed the decrease in mean drag value with increasing Reynolds number due to shear thinning effects. The forced oscillations result in shedding of vortices at Reynolds numbers lower than the critical Reynolds number to observe shedding in a fixed cylinder.

8:52AM H08.00005 Diving into a shear-thickening bath, PHILIPPE BOURRIANNE, Mechanical Engineering, MIT, ROBERT E. COHEN, Chemical Engineering, MIT, GARETH H. MCKINLEY, Mechanical Engineering, MIT — Shear-thickening fluids, made of suspensions of micro or nanoparticles, react to imposed excitations with a tunable behavior. At low shear-rate, they flow like a Newtonian or weakly shear-thinning liquid, whereas their viscosity rapidly increases following a more rapid perturbation. Due to this enhanced dissipation, shear-thickening fluids are known for their remarkable ability to absorb energy during collisions. When a solid object impacts a bath of shear-thickening fluid, the initial velocity determines the different settling regimes that are observed. We will describe these different regimes with regard to the rheological properties of the shear-thickening liquid and the characteristics of the impacting object. A few surprising observations could be noticed. First, a high velocity is not always the best way to penetrate such suspensions. Under such conditions, an appropriately-shaped fast-moving object can also bounce during the impact due to the shear-thickening behavior. By comparing the deceleration of an object into a viscous Newtonian and a shear-thickening liquid, we will explain the spectacular properties of shear-thickening during a collision.

9:05AM H08.00006 Dynamic Wetting Failure in Shear-Thinning and Shear-Thickening Liquids, VASILEIOS CHARITATOS, WIESLAW SUSZYNSKI, Department of Chemical Engineering and Materials Science, University of Minnesota, MARCIO CARVALHO, Department of Mechanical Engineering, PUC-Rio, SATISH KUMAR, Department of Chemical Engineering and Materials Science, University of Minnesota — Dynamic wetting failure in shear-thinning and shear-thickening liquids is examined in this work. Flow visualization experiments using a curtain-coating geometry suggest that shear thinning postpones the onset of wetting failure and the resulting air entrainment. To advance fundamental understanding of the underlying physical mechanisms, a hydrodynamic model consisting of liquid displacing air in a rectangular channel in the absence of inertia is developed. Both shear thinning and shear thickening are considered by using Carreau-type models to describe the liquid rheology. Steady-state solutions are calculated using the Galerkin finite-element method and the critical capillary number where wetting failure occurs is identified. Shear thinning is found to postpone the onset of wetting failure whereas shear thickening is found to promote it. The underlying mechanism involves thickening/thinning of the air film as a consequence of shear thinning/thickening of the liquid and the tangential stress balance.

9:18AM H08.00007 Enhanced speed of a falling sphere in pseudo-plastic fluid with ultrasound irradiation. MINORU IWAMURO, TOMOAKI WATAMURA, KAZUYASU SUGIYAMA, Osaka Univ — We experimentally investigated the effect of ultrasound irradiation on a falling sphere in pseudo-plastic fluid. The falling velocity is measured via an image processing technique. We performed experiments with parametrizing sphere diameter, fluid properties, ultrasound intensity, and its frequency. We found that the falling speed is enhanced by ultrasound irradiation, and the speed-up in the stronger pseudo-plastic fluid is much greater than that in the weaker one. We conclude that the speed-up ratio is relevant to the ratio of the viscosity and length scales involved in the system.

9:31AM H08.00008 The death of the fluid mechanical sewing machine: viscoelastic effect. BERNARDO PALACIOS, Universidad Nacional Autonoma de Mexico, STEPHEN W. MORRIS, University of Toronto, ROBERTO ZENIT, Brown University — In this work we study the fall of a viscous filament onto a moving surface. While the problem has been studied extensively for Newtonian fluids, referred to as the fluid-mechanical sewing machine, the effects of considering other complex fluids have not been explored to date. We replicate the setup used for Newtonian fluids, issuing a fluid filament from a nozzle from certain vertical distance from a moving substrate to observe it coil and stretch simultaneously. The fluid considered is, instead, a Boger fluid (viscoelastic but with constant viscosity). Our experiments show that, for similar conditions, the coiling instability does not appear if the fluid has sufficient elasticity. In most cases, the fluid mechanical sewing machine effect is not observed. Instead, a largely stable fluid catenary is observed. The shape of the catenary is characterized considering a Deborah number and a dimensionless height. A map of the conditions to kill the fluid mechanical sewing machine effect is presented in terms of these two dimensionless groups.

9:44AM H08.00009 Dynamics of viscoelastic films in reverse squeeze flows. BAVAND KESHAVARZ, ERICA LAI, GARETH MCKINLEY, NIELS HOLTE-ANDERSEN, MIT, MECHE/DNSE COLLABORATION — In many industrial and biological applications thin films of complex fluids act as lubricating layers between solid boundaries. Upon the separation of these boundaries, the kinematics of the flow generates large pressure gradients leading to high values of adhesive forces. We perform a detailed study on these phenomena using different relaxation times and elasticity moduli. The liquid is initially at rest in the gap between two circular discs. The discs are then separated from each other with an exponentially increasing velocity, ensuring a constant nominal value of stretch rate during the test. Adhesion force measurements show a rate-dependent peak force that scales with the elastic modulus of the liquid followed by an exponentially decaying tail. We show that with a proper scaling all of the measured peak forces for different viscoelastic liquids follow a single master curve. Coupling the simplified kinematics of this reverse squeeze flow with the viscoelastic constitutive equation leads to a simple lubrication model. We show that the predictions from the model agree well with the experimental measurements. Results from this study can shed light on the dynamics of liquid adhesion in complex fluids.

9:57AM H08.00010 A novel non-linear one-dimensional model for viscoelastic lubricants. LUCA BIANCOFIORE, HUMAYUN AHMED, Bilkent University — Lubrication is essential to improve the performance of sliding surfaces. Power transmission in mechanical and biological systems relies on proper lubrication to minimize wear and energy losses. However, most practical applications involve conditions that cause or require the lubricant to exhibit viscoelastic behavior. In this study a novel 1D viscoelastic Reynolds equation is derived based on the Oldroyd-B constitutive relation. It comprises a system of five 1D equations describing the pressure, velocity and shear stress distribution in the film. The model is compared with direct numerical simulations of thin films for different geometries. The results are in good qualitative and quantitative agreement indicating the simplified model is valid within the context of lubrication theory. Firstly, the pressure presents strong variations as the lubricant elasticity becomes significant, but stagnates as the polymer relaxation time becomes slow compared to the characteristic flow time. Secondly, the net film pressure is shown to be a superposition of a Newtonian and viscoelastic component. The viscoelastic component depends on the surface geometry. Surfaces with constant slope exhibit a pressure decrease, whereas the opposite effect is observed in parabolic solids.

10:10AM H08.00011 Effect of viscoelasticity on the stability characteristics of a drying polymer solution. GEORGE KARAPETSAS, ATHANASIOS VADARLIS, Aristotle University of Thessaloniki — We investigate the stability of an evaporating liquid film which consists of a polymeric solution with a volatile solvent. Besides solutocapillary and thermal Marangoni effects, an important factor affecting the flow, which is often neglected in the literature, is the viscoelastic character of the polymeric solutions typically encountered in practical applications. During the drying process, the concentration of the solvent continuously decreases thus rendering the non-Newtonian character of the solution increasingly important. Here, we develop a model fully accounting for the viscoelastic behaviour and dynamically varying rheological properties of the liquid film. We use a finite element formulation to solve the time-dependent problem and perform a linear stability analysis employing the quasi-steady state approximation, in the limit of slow evaporation. Our numerical results indicate that the increasingly important effect of viscoelasticity destabilizes the flow and also leads to patterns with smaller wavelengths. We discuss the mechanisms which give rise to these instabilities.

10:23AM H08.00012 Flow of a Shear Thickening Micellar Fluid Past a Falling Sphere. SHUIJAN WU, HADI MOHAMMADGHOUSHKI, Florida State University, FLORIDA STATE UNIVERSITY TEAM — In this work, we present the first quantitative measurements of a dilute shear thickening micellar solution past a falling sphere. The micellar solution consists of cetyltrimethylammonium bromide and 5-methyl salicylate (CTAB/5MS) in de-ionized water and it exhibits shear thickening behavior. This CTAB/5MS micellar solution forms un-entangled rod-like micelles at equilibrium. It is found that the drag coefficient for the falling sphere is similar to that of a Newtonian fluid at a vanishingly small Reynolds number (Re = 0.03). However, falling spheres experience a significant drag reduction for conditions that correspond to 0.09 ≤ Re ≤ 9.86. Moreover, an unusually extended wake which spans over a long distance downstream of the sphere is detected by particle image velocimetry. These unusual results could be rationalized by invoking the phenomenon of flow induced structure formation. We hypothesize that strong shear and/or extensional flows around the falling sphere could trigger the aggregation of rod-like micelles into giant worm-like structures. Such worm-like micelles may induce significant sphere drag reduction and extended elastic wakes in the rear of sphere. This interpretation is consistent with the steady shear and transient extensional flow measurements.

Monday, November 25, 2019 8:00AM - 10:36AM – Session H09 Aerodynamics: General 213 - John Farnsworth, University of Colorado Boulder
8:00AM H09.00001 Enhancement of gust using jet at trailing edge of airfoil: A novel technique. DIPENDRA GUPTA, JAYWANT H. ARAKERI, Department of Mechanical Engineering, Indian Institute of Science, Bangalore — Sudden and sharp change in flow velocity, termed as a gust, is an important parameter to study flight performance, especially of micro-air vehicles (MAVs) and aircraft. There have been several techniques to create gusts in a wind tunnel including using pitching foils at the entrance of the test section. One conventional method is using two airfoils with a certain spacing to create a gust. The model aircraft to be tested is placed downstream between the pitching foils. The main limitation with this technique is the low gust intensity (lg) that can be achieved. We propose a new method to enhance lg using jet at the trailing edge of the pitching foils. Numerical simulation shows the gust intensity, using the proposed method, to increase by 2-7 times compared to that by conventional techniques for a particular Re, jet velocity and the range of reduced frequencies considered. Moreover, the spacing of foils ensures shear-free smooth flow in the near region surrounding the model, unlike some existing methods for gust enhancement. This technique provides a simple, economical and controlled way to study gust response of MAVs and aircraft in wind tunnels.

8:13AM H09.00002 The effects of freestream turbulence on the pressure distributions and lift characteristics of airfoil. LEON LI, R. JASON HEARST, Norwegian University of Science and Technology — Airfoils employed in engineering applications are often subjected to significant flow variations which can have adverse impacts on their aerodynamic performance and structural stability, for example a wind turbine operating in an atmospheric boundary layer or an aircraft in flight. The impact of these incoming (or freestream) variations is presently not well understood. To gain a better understanding, one must explore a wide parameter space of freestream parameters. This study uses 9 different passive grid configurations to alter the freestream turbulence (FST) in a wind tunnel in order to measure the impact of FST on the pressure distribution and lift characteristics of a NREL S826 reference airfoil. The FST intensity ranges from 0.5% to 5.4%, and the chord-normalized integral length scale varies between 0.07 and 0.24. The chord Reynolds number (Re) was varied between 200-400k. Preliminary results show that an increase in turbulence intensity increases both the maximum lift coefficient and the lift slope. The latter observation contrasts with some results reported in the literature with a smaller FST parameter space number (Re) was varied between 200-400k. Preliminary results show that an increase in turbulence intensity increases both the maximum lift coefficient and the lift slope. The latter observation contrasts with some results reported in the literature with a smaller FST parameter space number (Re) was varied between 200-400k. Preliminary results show that an increase in turbulence intensity increases both the maximum lift coefficient and the lift slope. The latter observation contrasts with some results reported in the literature with a smaller FST parameter space.

8:26AM H09.00003 Collaborative Experiments and Simulations of an Unsteady Free-Jet Wind Tunnel for the Study of Gust Interactions. JOHN FARNSWORTH, KENNETH JANSEN, DASHA GLOUTAK, MARK BLANCO, University of Colorado Boulder — An unsteady wind tunnel facility was recently developed at the University of Colorado by incorporating a set of counter-rotating louver vanes at the inlet to the low-speed, open-return wind tunnel. The facility was designed such that the wind tunnel can be reconfigured for testing in both a standard closed test-section configuration and an open test-section or free jet configuration. In both configurations, the wind tunnel can operate with maximum test section velocities up to 30 m/s and an unsteady peak to peak amplitude on the order of 50% of the maximum. High fidelity computational fluid dynamics simulations of the unsteady wind tunnel facility were performed and are validated against experimental measurements. Operating the facility in the closed configuration produces a velocity perturbation that propagates through the test-section nearly instantaneously and thus can be assumed to be purely unsteady. In contrast, the open test-section or free jet configuration produces a velocity perturbation that propagates near the mean convective speed of the flow through the excitation of vortical structures in the surrounding shear layer.

8:39AM H09.00004 Computational Fluid Dynamic Simulations of a Finite NACA 0015 Wing in an Unsteady Flow. MARK BLANCO, DASHA GLOUTAK, JOHN FARNSWORTH, KENNETH JANSEN, University of Colorado Boulder — Computational fluid dynamic simulations were performed for a finite span NACA 0015 rectangular wing section subjected to an unsteady surging flow in a simulated, open test-section or free jet wind tunnel. The full wing and wind tunnel facility was completely modeled and simulated for accurate comparison to collaborative experimental investigations being performed in parallel. At moderate to high angles of attack the flow over the wing section is observed to undergo periodic, three-dimensional separation and reattachment as the surging flow decelerates and then accelerates, respectively. A detailed analysis of the three-dimensional flow field behavior is discussed focusing on the time varying response of the flow field, surface pressure distribution, and wall shear stress.

8:52AM H09.00005 Experimental Measurements of a Finite NACA 0015 Wing in an Unsteady Flow as Compared to Theory. DASHA GLOUTAK, EMANUELE COSTANTINO, MARK BLANCO, KENNETH JANSEN, JOHN FARNSWORTH, University of Colorado Boulder — Force, moment and velocity measurements of a semi-span, NACA 0015 rectangular wing subjected to unsteady flow are compared to classical surging airfoil theory. Unsteady streamwise flow, generated by a louver system at the wind tunnel inlet, consisted of maximum velocity amplitudes of 40% at frequencies up to 3Hz, with mean chord Reynolds Number below 150,000. These sinusoidal velocity gusts were imposed on the wing in the closed test section and free jet wind tunnel configurations. In the former, velocity changes occurred instantaneously over the entire chord length of the wing, and in the latter the velocity changes propagated at the gust’s convective speed. Mini-sweep and unsteady lift coefficient responses were compared to Isaacs’ unsteady airfoil theory, which details the lift behavior of an infinite airfoil at constant angle of attack with a variable streamwise velocity.

9:05AM H09.00006 Boundary Layer Characterization of a NACA-0012 Airfoil Plunging in Uniform-Shear Flow using 1c-MTV. MITCHELL ALBRECHT, AHMED NAGUIB, MANOOCEHRO KOOCHESFAHANI, Michigan State University — Non-uniform approach flows can occur in environments through which aircraft navigate, such as the air wake of an aircraft carrier or aircraft formations. However, few studies have investigated the effects of viscous shear approach flow on airfoils. Our previous work shows that, in a Galilean reference frame, the lift coefficient on a NACA-0012 airfoil plunging in uniform-shear flow is greater than that of a stationary airfoil under the same flow conditions at near-stall positive angles of attack. To elaborate on this deviation from quasi-steady conditions, the current work examines the difference in lift behavior by characterizing the boundary layer around the plunging airfoil in uniform-shear flow. Single-component molecular tagging velocimetry is used to measure the streamwise velocity component of the flow on the suction side of the airfoil surface. Various boundary layer characteristics will be presented for the plunging airfoil as it traverses across the shear layer, and compared with the stationary airfoil at the same cross-stream position, flow conditions, and effective angles of attack.

9:18AM H09.00007 Finite Wing Hydrodynamic Forces during Water-to-Air Interface Transition. WARREN WEISLER, RAJMOHAN WAGHELA, DR. KENNETH GRANLUND, DR. MATTHEW BRYANT, North Carolina State University — Wings are used for numerous applications in both air and water and their lift generation in either domain is well understood. However, the lift generated by a wing when it is transitioning out of water and into air has not been quantified to date. This experimental study aims to examine the lift generated by a wing as it is translated through the water-to-air interface. Studies on egress velocities of 0.2 - 0.75 m/s were conducted to examine the effect of velocity on lift generation over a range of angles of attack from 0-10 degrees. The lift generated by a rectangular NACA 0015 wing with a chord of 10 cm and an aspect ratio of 4 was dependent on velocity. At the "slower" velocities there is a spike in lift when the wing leading edge nears the water surface, sometimes more than double the steady values. As the speed increases, the spike in lift disappears and lift decreases before the leading edge even reaches the surface. The results from the angle of attack testing show that the transition profile appears to scale with angle of attack.

9:31AM H09.00008 Three Dimensional Simulation of Dynamic Stall on a Dynamically Pitching Airfoil at Re = 12,000. HARRY WERNER IV, DOUGLAS BOHL, BRIAN HELENBROOK, CHUNLEI LIANG, Clarkson University — Dynamic stall (DS) is a flow separation phenomenon affecting airfoils that experience dynamic changes in Angle of Attack (AOA) beyond the airfoil’s static stall angle. Passive control of DS could extend the lifespan and efficiency of rotors, wind turbine blades, and other fixed and rotating geometric aerostructures. The development of effective methodologies for the passive control of dynamic stall requires an in-depth understanding of the fundamental flow physics governing DS phenomena. This work examines the fundamental flow phenomena of dynamic stall through Large Eddy Simulation (LES) of a dynamically pitching NACA 0012 airfoil at low Reynolds Numbers (Re = 12,000) and a constant nondimensional pitch rate of $\Omega^* = 0.1$. The simulation is a pitch and hold scenario, whereby the airfoil is rotated from 0 to 50$^\circ$AOA at a non-dimensional pitch rate of 0.1. The airfoil is held static at 50$^\circ$AOA for an additional 10 chord times to observe vortex formation and convection. Results are compared to experimental measurements.

9:44AM H09.00009 Unsteady spectra of velocity field for a canonical dynamic stall process. ROHIT GUPTA, University of Illinois at Urbana-Champaign, SABRINA HENNE, KAREN MULLENBERS, cole Polytechnique Fédérale de Lausanne, PHILLIP ANSELL, University of Illinois at Urbana-Champaign — Dynamic stall is a multiscale phenomenon that is commonly associated with airfoils undergoing rapid maneuvers. The knowledge of the dominant modes of instability in the flow field is critical for the design of effective actuation strategies for the control of dynamic stall. The objective of the present investigation was to extract the time-dependent spectral content of the velocity field about a NACA 0012 airfoil model subjected to a linear pitch-up maneuver in a water tunnel at a chord-based Reynolds number of 10^5. This objective was achieved through a novel strategy involving a combination of empirical mode decomposition and the Riesz transformations. The velocity field was acquired using high-fidelity, time-resolved particle image velocimetry. The acquired velocity measurements were processed through the empirical mode decomposition algorithm to obtain a set of oscillatory modes, known as the intrinsic mode functions, and an underlying trend, termed as the residue. The dominant amplitudes and frequencies were extracted through a direct application of the Riesz transform. The resulting velocity field spectra were then analyzed at several critical stages of the dynamic stall process.

1This study is funded by the Air Force Office of Scientific Research as part of the International Student Exchange Program (ISEP) under Agreement # FA9550-15-1-0277 in the Unsteady Aerodynamics and Turbulent Flows portfolio, monitored by Dr. Gregg Abate.

9:57AM H09.00010 Evaluation of the unsteady aerodynamic forces of an oscillating airfoil undergoing dynamic stall using impulse theory. FIRAS SIALA, JAMES LIBURDY, Oregon State University — The unsteady forces generated by a heaving and pitching airfoil are evaluated from velocity fields using the finite-domain vortex impulse theory. Time-resolved velocity fields are obtained experimentally using two-component particle image velocimetry measurements at reduced frequencies of $k = f c/U = 0.060.16$ (where $f$ is oscillation frequency, $c$ is chord length and $U$ is free stream velocity) with heaving and pitching amplitudes fixed at $h_0 = 0.6c$ and $\theta_0 = 75^\circ$, respectively. The concept of moment-arm dilemma associated with the impulse equation is revisited to shed light on its physical impact on the calculated forces. It is shown that by selecting an objectively defined origin of the moment-arm, the finite-domain impulse force formulation can be greatly reduced to two terms that have a clear physical interpretation: (i) the time rate of change of the impulse of vortical structures within the control volume and (ii) the Kutta-Joukowski force that indirectly captures the contributions of vortical structures outside of the control volume. Furthermore, it is shown that for the reduced-form of the impulse equation to be valid, a critical distance of 0.85c or greater from the airfoil trailing edge to the downstream control volume boundary is required.

10:10AM H09.00011 Investigation of compressibility effects on a plunging airfoil under dynamic stall conditions. RENATO FUZARO MIOTTO, University of Campinas, DATTA GAITONDE, The Ohio State University, WILLIAM ROBERTO WOLF, University of Campinas, MIGUEL VISBAL, Air Force Research Laboratory — Large-eddy simulations are performed to study the compressibility effects on an airfoil under deep dynamic stall condition. In the present work, an SD7003 airfoil in plunging motion is considered at a chord Reynolds number of $Re = 60,000$ and freestream Mach numbers $M = 0.1$ and 0.4. These conditions aim to meet the current renewed interest in low- and moderate-Reynolds number unsteady aerodynamics, which finds applications in the design of small unmanned air vehicles and micro air vehicles. The current numerical methodology has already been validated for $M = 0.1$ and is herein extended for other flow regimes. In addition, modal decomposition techniques are also employed to analyze the complex off-surface flow structures associated with the dynamic stall, and to assess its onset mechanism for different compressible scenarios.

10:23AM H09.00012 Blunt nose airfoils for improved stall performance and transonic aerodynamics. YUXIN ZHANG, WSU, MATTHEW KRALJIC, ZVI RUSAK, Rensselaer Polytechnic Institute — We numerically study the aerodynamic performance of blunt airfoils in terms of both the delay of critical Mach number for transonic shock waves to higher values and the increase of stall angle of attack at low subsonic speeds. The approach is motivated by the optimal critical airfoils developed by Schwedemman et al. (ZAMP 1993) and the recent results on the delay of stall by Kraljic & Rusak (PRFluids 2019). The nose of the airfoils is given by a canonical shape $y = (ax)^{1/\delta}$, where $\delta \geq 2$. The effect of changing the airfoils nose parameter $a$, thickness ratio $\delta$, and location of maximum thickness $x_1/c$ from leading edge on the wave drag and stall angle of attack are determined. Increasing $a$ and decreasing $x_1/c$ at a fixed $\delta$ improves lift generation and improves performance at subsonic and transonic speeds for application in wings of transport jet airplanes, rotors of helicopters, and rotating turbines.
8:00AM H10.00001 Linear Reduced-order Model based on Particle-image-velocimetry Data of Flow Field around Airfoil Controlled by Plasma Actuator. 1 KOKI NANKAI, KENTO SUZUKI, ATSUSHI KOMURO, Tohoku University, TAKU NONOMURA, Tohoku University, Presto, JST, KEISUKE ASAI, Tohoku University — A linear reduced-order model of flow fields around an airfoil controlled by a dielectric-barrier-discharge plasma actuator (DBDPA) is constructed based on particle image velocimetry (PIV) data. Velocity field data around a NACA0015 airfoil with random input by the DBDPA at the chord Reynolds number of 64,000 were acquired using PIV in a wind tunnel test. Subsequently, lower-dimensional description of the data was obtained by proper orthogonal decomposition (POD). The coefficient matrix of the linear model was computed using the least-squares approximation with the POD-mode coefficients and control input data, similar to dynamic mode decomposition with correlation. The effects of the control input component of DBDPA on the low-dimensional velocity fields reconstructed by the first ten POD modes were investigated from the input matrix. It is demonstrated that the velocity fields are more sensitive to the input change than the average value of the input. This result implies that the present model can show the well-known flow control characteristic that DBDPA with intermittent actuation such as the burst mode or nanosecond-pulse-driven mode is more effective for the separation control of flow fields than continuous actuation.

8:13AM H10.00002 Reduced-order Modeling and Estimation for Buoyancy-driven Flow Control. SANJANA VIJAYSHANKAR, Department of Electrical and Computer Engineering, University of Minnesota, PIYUSH GROVER, Mechanical and Materials Engineering, University of Nebraska-Lincoln, SALEH NABI, Mitsubishi Electric Research Labs — We consider the problem of data-driven reduced-order modeling and state estimation of buoyancy-driven turbulent flows in the built environment. First, we investigate the efficacy of data-driven techniques such as Eigensystem Realization Algorithm (ERA) and Dynamic Mode Decomposition (DMD) for systems described by Boussinesq equations. The resulting reduced-order models are suitable for real-time control applications. We employ these reduced-order models to construct reduced-order observers for systems operating in forced and mixed convection regimes. Exhaustive numerical simulations (both DNS and RANS) in the context of energy efficient buildings and internal flows are provided to validate the accuracy and computational benefits of this approach.

8:26AM H10.00003 Machine learning of sequential data for non-intrusive reduced-order models. ROMIT MAULIK, Argonne National Laboratory, ARVIND MOHAN, Los Alamos National Laboratory, SANDEEP MADIREDDY, BETHANY LUSCH, PRASANNA BALAPRAKASH, Argonne National Laboratory, DANIEL LIVESCU, Los Alamos National Laboratory — We study implementations of machine learning strategies for time-series data for non-intrusive reduced-order models of non-linear partial differential equations. Our reduced space is obtained with an $L_2$-optimal proper orthogonal decomposition (POD) with subsequent truncation. We then study the performance of these techniques for systems that require closure due to insufficient resolution of all of the energy in the system. Accurate non-linear dynamics in POD space are learned through recurrent neural networks and neural ordinary differential equations which utilize history, analogous to the Mori-Zwanzig formalism, to retain the effects of the unresolved modes. We also detail the use of attention to maintain the precision of learning for long-term prediction horizons and conclude by discussing distributed hyperparameter search strategies using asynchronous model-based Bayesian optimization.

8:39AM H10.00004 A Simple POD-Galerkin Model Based on Computational or Experimental Data of Flows with Moving Boundaries. MINGJUN WEI, BOLUN XU, HAOTIAN GAO, Kansas State University, JOHN HRYNUK, Army Research Lab — POD-Galerkin projection has been popular as a systematical approach for model order reduction of a complex dynamic system such as a fluid flow described by Navier-Stokes equations. However, the classical POD-Galerkin projection is derived only in a fixed domain, which limits its application on many fluid-structure interaction problems featuring moving boundaries or morphing domains. We have developed a simple modification to allow an easy implementation accounting for structural effects to extend the application of POD-Galerkin projection to a broad range of flows with moving boundaries. Recently, the modified approach was further improved to achieve better accuracy near the moving solid boundaries. The improved approach has been applied not only to direct numerical simulation data but also to experimental data. The experimental data includes the PIV measurement of the flow field for a rotating ellipse with incoming flow in a closed-loop wind tunnel.

8:52AM H10.00005 Flow Field Reconstruction and Filtering Using Spectral Proper Orthogonal Decomposition. AKHIL NEKKANTI, OLIVER SCHMIDT, University of California San Diego — The spectral variant of proper orthogonal decomposition (SPOD) decomposes a flow field into orthogonal modes that evolve coherently in both space and time, and that are optimally ranked by their energy. Just like in the case of standard proper orthogonal decomposition (POD), SPOD permits the reconstruction of the data from the modes and their expansion coefficients, and benefits from the optimality of the expansion. In this contribution, we show how the fact that SPOD is conducted in the frequency domain can be leveraged to achieve a number of goals. In particular, we use truncated series reconstructions and frequency-dependent scaling to facilitate low-rank approximations, band-pass filtering, pre-whitening and de-noising of experimental data. It is demonstrated, for example, that even a rank-1 SPOD approximation, which retains only one mode per frequency, is capable of capturing the significant dynamics of a fully turbulent flow field. Finally, we show how this iterative procedure can be employed for gappy data reconstruction. Two test cases are considered: large eddy simulation data of a turbulent jet and particle image velocimetry fields of the turbulent wake behind a flat plate at high angle of attack.

9:05AM H10.00006 Towards reduced-order SPOD-Galerkin models for turbulent flows. TIANYI CHU, OLIVER T. SCHMIDT, Department of Mechanical and Aerospace Engineering, Jacobs School of Engineering, UCSD, 9500 Gilman Drive, La Jolla, CA 92039-0411, USA — We explore the use of spectral proper orthogonal decomposition (SPOD) to construct reduced-order Galerkin models of turbulent flows under a linear time-invariant approximation. The motivation behind this particular modeling approach is the theoretical correspondence between the empirical SPOD technique and operator-based resolvent analysis, which considers optimal responses to a stochastically forced linear system. For the example of a Mach 0.9 turbulent jet, a recent study found a surprising agreement between SPOD modes computed from large-eddy simulation data and mean flow-based resolvent analysis. The same data is used in this work. Since the SPOD modes are orthogonal in a space-time inner product, the time-domain Galerkin model requires an oblique projection of the data onto the non-orthogonal modal basis. The resulting reduced-order model for the expansion coefficients is advanced in time by the linearized Navier-Stokes operator, and closed-loop control techniques, such as minimal-energy feedback control, are employed to calibrate the reduced-order model. To offset the difference between the linear approximation and the true, non-linear solution, we further incorporate the forcing statistics, inferred from applying the discrete linear operator to the data, into the model.
9:18AM H10.00007 Fast Greedy Optimization of Sensor Selection in Measurement with Correlated Noise1, KEIGO YAMADA, YUJI SAITO, Tohoku University, TAKU NONOMURA, Tohoku University, Presto, JST, KEISUKE ASAI, TOHOKU UNIVERSITY, Tsuchiura, — Efficiently leveraging limited sensor data in reduced-order models (ROMs) is key to enabling real-time control of a range of fluid flows. Two primary challenges to achieving this goal are: i) while the ROM evolves on a low-dimensional space, sensor data is typically related to the ROM via an intermediate step that involves the high-dimensional fluid state, ii) although a physical interpretation of the ROM state space may be derived, it is rarely obvious how to directly relate physical measurements to this low-dimensional representation. To address both challenges, we propose a flow-field estimation methodology where the sensor data is directly mapped to the ROM state space without involving the high-dimensional flow state. The flow-field can be efficiently recovered via the ROM approximation, if desired. We employ a neural-network architecture that learns the nonlinear mapping between the sensors and space. We emphasize that the proposed estimation framework is agnostic to the ROM employed, and can therefore be incorporated into ROMs derived by Galerkin projection, regression, etc. Our methodology is demonstrated on problems involving parametric 1D diffusion and 2D flow over an airfoil.

9:31AM H10.00008 Integrating sensor data into reduced-order models with deep learning, NIRMAL JAYAPRASAD NAIR, ANDRES GOZA, University of Illinois at Urbana-Champaign — Efficiently leveraging limited sensor data in reduced-order models (ROMs) is key to enabling real-time control of a range of fluid flows. Two primary challenges to achieving this goal are: i) while the ROM evolves on a low-dimensional space, sensor data is typically related to the ROM via an intermediate step that involves the high-dimensional fluid state, ii) although a physical interpretation of the ROM state space may be derived, it is rarely obvious how to directly relate physical measurements to this low-dimensional representation. To address both challenges, we propose a flow-field estimation methodology where the sensor data is directly mapped to the ROM state space without involving the high-dimensional flow state. The flow-field can be efficiently recovered via the ROM approximation, if desired. We employ a neural-network architecture that learns the nonlinear mapping between the sensors and state space. We emphasize that the proposed estimation framework is agnostic to the ROM employed, and can therefore be incorporated into ROMs derived by Galerkin projection, regression, etc. Our methodology is demonstrated on problems involving parametric 1D diffusion and 2D flow over an airfoil.

9:44AM H10.00009 Determinant based Fast Greedy Optimization on Sparse Sensor Selection1, YUJI SAITO, KEIGO YAMADA, Tohoku University, TAKU NONOMURA, Tohoku University, Presto, JST, KEISUKE ASAI, Tohoku University, DAISUKE TSUBAKINO, YASUO SASAKI, Nagoya University — The problem of optimally placing sensors to reduce calculation cost and reconstruction error arises naturally in scientific experiments. It is especially difficult to speedily select optimal sensors when the number of sensors is larger than POD modes. In this study, the authors have developed and proposed an extended determinant-based greedy algorithm based on a QR discrete empirical interpolation method (QDEIM) for the optimal sensor placement problem. The key point of this idea is that optimal sensors are obtained by the QDEIM method until the number of sensors is equal to POD modes. After that, new sensors are calculated by applying both of the determinant formula and matrix inversion lemma. We demonstrate the effectiveness of this algorithm on datasets related to climate science, and compare all calculation results; random sensors, convex approximation and a previously proposed QR algorithm in addition to the determinant-based greedy algorithm. We show that the calculation time of the proposed extended determinant-based greedy algorithm is faster than that of other methods with almost the same level of reconstruction error.

9:57AM H10.00010 Network-based identification of influential structures to modify turbulent flows1, MURALIKRISHNAN GOPALAKRISHNAN MEENA, KUNIHKO TAIRA, University of California, Los Angeles — The nonlinear interactions among vortical structures in turbulence make their characterization and control a challenge. We use network theory to formulate and characterize the web of interactions among vortical elements in two- and three-dimensional decaying isotropic turbulence. The nodes of these networks correspond to vortical elements in the flow field and the connections among them are weighted by the induced velocity. Network-based community detection algorithm is used to identify network connector (inter-community) and peripheral (intra-community) structures that resemble shear-layer and vortex-core type structures, respectively. We assess the influence of these structures to the neighboring vortical structures by performing DNS with added impulse perturbations to the identified network-based structures. We compare our findings with those from traditional forms of structure identification and observe enhanced turbulent mixing with the present approach. We discuss the implications of the present network-based technique for active flow control.

10:10AM H10.00011 Physics-informed Echo State Networks for the prediction of chaotic systems, LUCA MAGRI, FRANCISCO HUHN, University of Cambridge, NGUYEN ANH KHOA DOAN, Dept. of Mechanical Engineering, Technical Univ of Munich — We suggest Echo State Networks (ESN), a data science technique, to predict the evolution of chaotic dynamical systems, namely those of high-fidelity fluid dynamics simulations, LES and DNS. Data generated from high-fidelity simulations carry high computational cost and thus only small amounts are available. While this usually poses a limitation to data science techniques – unlike the traditional big data, this problem lives in the world of “small data” –, this can be balanced by leveraging physical knowledge of the system in study, that is, while ESNs can be trained purely on past observations, their performance can be improved, for example, by including a loss term that represents the system’s physics and penalizes non-physical predictions in the training phase. We explore the characteristics and performance of physics-informed ESN models, from a nonlinear dynamics point-of-view, in reproducing chaotic dynamical systems. Finally, we look into potential applications to fluid dynamics problems, such as prediction of extreme events or sensitivities of time-averaged cost functionals.

10:23AM H10.00012 Dimensionality Reduction and Reduced Order Modeling for Traveling Wave Physics1, ARIANA MENDIBLE, ALEKSANDER ARAVINK, University of Washington, WES LOWRIE, STEVEN BRUNTON, J. NATHAN KUTZ, University of Washington — Large scale spatiotemporal data are ubiquitous across many fields of science and engineering, especially in fluids. Standard dimensionality reduction techniques based on the singular value decomposition (SVD) often fail to provide a compact representation of traveling waves because the SVD is inherently a space-time separation of variables. This necessitates a data-driven method to decompose and reduce spatiotemporal systems with multiple traveling waves. In this work, we investigate alternative approaches to dimensionality reduction that are designed specifically to separate and represent interpretable traveling wave structures in a low-dimensional form. Using a shifted SVD, we formulate an unsupervised, optimization-based framework for identifying parsimonious wave speed models from many candidate models. We demonstrate our method on example systems which pose challenges of non-periodicity, nonlinearity, and changing wave speed.

1HDTTRA1-18-1-0038
8:00AM H11.00001 An Experimental Investigation of Surfactant Effects on the Wave Characteristics of Annular Flows\textsuperscript{1}, ANDRIUS PATAPAS, VICTOR VOULGAROPOULOS, VALERIA GARBIN, RONNY PINI, CHRISTOS MARKIDES, OMAR MATAR, Imperial College London, KARL ANDERSON, Shell — While a wide scope of research has been performed in the field of multiphase flows, the study of surface active agents in gas-liquid annular flows has lagged despite their ability in considerably improving heat and mass transfer rates. More detailed insight is still needed to promote quantitative interpretations of the surfactant-induced effects on the wave characteristics and entrainment properties of these thin films. In this work, we study water-air annular pipe flows in both the presence and absence of a water-soluble fluorescent surfactant. The liquid Reynolds numbers, based on the film properties, range between 400 to 1500. We perform structured planar laser-induced fluorescence (S-PLIF) measurements to accurately obtain film-thickness measurements and reveal the temporal characteristics of the waves. We further explore the differences on the entrainment rates and size of the bubbles in the liquid films for both cases, by visualising the flow from two observation angles. Surfactant-tracking diagnostic methods are also currently being developed.

8:13AM H11.00002 Laser Cantilever Anemometry for highly resolved velocity measurements in fluids, JAROSLAW PUCZYLOWSKI, University of Oldenburg, MEASUREMENT SCIENCE ENTERPRISE MSE COLLABORATION — Laser Cantilever Anemometry is a new and high-resolution measurement method for determining the velocity vector of a fluid. A micro-structured silicon cantilever serves as a drag body that is set into the flow. The forces acting on the cantilever, which are exerted by the moving fluid particles, cause the cantilever to bend or twist. With the help of the laser pointer principle, this deformation can be detected and finally recalculated into a velocity vector in two dimensions. The measuring principle is characterized by a very high temporal and spatial resolution (approx. 100m at 100kHz). In the recent past a sensor was developed and tested, which uses this measuring method. The so-called 2d-LCA (2d-Laser Cantilever Anemometer) was extensively and successfully used under different laboratory conditions. The current version of the 2d-LCA has the size of a highlighter and is operated via USB-C or Bluetooth. This compact design is extremely portable and allows the use in difficult to access areas. In addition, all hardware components of the 2d-LCA are made of Invar (Alloy36), which has a very low coefficient of thermal expansion. This avoids heat-related drift and leads to a very stable signal. At the The 72nd Annual Meeting of the American Physical Society’s Division of Fluid Dynamics (DFD), the measuring principle of the 2d-LCA will be explained in more detail and measurement results will be presented.

8:26AM H11.00003 Development of Focused Laser Differential Interferometry for Hypersonic Freestream Measurements\textsuperscript{1}, JOEL LAWSON\textsuperscript{2}, MALLORY NEET\textsuperscript{3}, JOANNA AUSTIN\textsuperscript{4}, California Institute of Technology — Focused laser differential interferometry (FLDI) is a non-invasive diagnostic capable of making localized density measurements with high temporal resolution. Its distinguishing feature for ground testing is diminished response away from the focal plane, thereby mitigating signal contributions from fluid not in the facility core flow. We first present a quantitative experimental validation of a ray-tracing scheme used to model the FLDI response. This is followed by some applications of the technique to Caltech’s hypersonic ground testing facilities: firstly, FLDI is applied to the Hypervelocity Expansion Tube (HET) to measure the freestream noise spectrum during test time, and relating this to the initial driver gas state as per the acoustic wave theory of Paull and Stalker [J. Fluid Mech., vol. 245, pp. 493-521, 1992]. Secondly, FLDI is used to track a laser-induced breakdown in the freestream of the T5 reflected shock tunnel, with the goal of measuring flow velocity and sound speed.

8:39AM H11.00004 Weighted Least squares density reconstruction for Background Oriented Schlieren (BOS)\textsuperscript{1}, LALIT RAJENDRAN, JIACHENG ZHANG, SALLY BANE, PAVLOS VLACHOS, Purdue University — Background Oriented Schlieren (BOS) is an optical technique used to measured density gradients by tracking the apparent distortion of a dot pattern. The density gradient field can then be spatially integrated to calculate the density field. The Poisson solver is currently the standard for density integration, but it is sensitive to noise in the gradient field. We address this limitation and improve the overall accuracy of the density integration process by employing a weighted least-squares (WLS) method. WLS performs the 2D integration of a gradient field by solving an over-determined system of equations. Weights are assigned to the grid points based on errors/uncertainties in the density gradient field to ensure that a less reliable measurement point is given less weight on the integration procedure. This method has been shown to increase the robustness of the integration in velocity-based pressure estimation, and in this study we will assess its suitability for BOS. We will assess the calculation of weights based on two methods: (1) based on the displacement uncertainty and (2) using a curl-free constraint on the density gradient field, as the underlying density field is a scalar. The contribution is an improved integration method for density estimation from BOS.

A quantitative analysis of the chemical evolution of an iodine plume using optical filtering, imaging spectroscopy, and schlieren imaging. SARAGORIO, ALEXANDRA RIVERA, MICHAEL HARGATHER, New Mexico Tech — The chemical evolution of an iodine plume was quantitatively analyzed using a dual high-speed camera imaging system and verified using imaging spectroscopy. The dual high-speed camera imaging system consisted of a parallel light lens schlieren system with a beamsplitter located after the knife-edge to send the light into two Phorion Mini AX cameras. Each camera imaged through an optical notch filter, one at 520 nm and one at 650 nm. The 520 nm and 650 nm filters correspond to the maximum absorption wavelength and zero absorption wavelength of the iodine absorption spectra, respectively. A turbulent plume, consisting of vaporized iodine and a carrier gas, was imaged in the dual camera system. The resulting image sets were processed to relate differences in pixel intensity to light absorption intensity of the developing plume. The plumes iodine concentration was then derived from the changes in absorption intensity. A validation system, using a Horiba MicroHR imaging spectrometer and a Phorion SA-X2 camera, measured the iodine plumes absorption spectra directly and verified the accuracy of the optical filtering technique. Results show the ability to perform simultaneous refractive imaging and species identification in a turbulent flow field.

**9:05AM H11.00006** Measurement of high frequency temperature fluctuations in high-pressure premixed combustion using laser Rayleigh scattering, HAN JUNE PARK, SANGEUN BAE, HYUNGROK DO, WONTAE HWANG, Seoul National University — In gas turbines, the high temperature and pressure combustion environment makes it difficult to measure physical properties such as flame characteristics. This measurement issue is also crucial when assessing combustion instability. Thermoacoustic combustion instability is known to occur when heat release and acoustic oscillations become in phase with each other. Due to the nature of heat release oscillation, modeling and measurement are difficult. To measure heat release oscillations, temperature fluctuation measurements are necessary. However, previous research in high temperature and pressure environments has been limited. In this study, we measured high frequency temperature fluctuations in high-pressure premixed combustion through density fluctuations, using non-intrusive laser Rayleigh scattering. The photon counting method was applied to quantify low intensity Rayleigh scattering. In addition, a high-speed camera was used to correlate the flame shape and combustion instability as pressure increases.

**9:18AM H11.00007** Planar spray visualization processing techniques and considerations, KYLE M. BADE, RUDOLF J. SCHICK, Spraying Systems Co., SPRAY ANALYSIS AND RESEARCH SERVICES TEAM — Techniques to visualize and characterize spray distributions include mechanical and optical methods. Planar laser illumination presents a non-intrusive and direct method to visualize and quantify the size, shape, and distribution of a spray across a known cross-section. The nuances of processing and interpreting the light intensity from polydisperse sprays can have a significant effect on the resulting relative distribution of the scattered light. Mie scattered light is proportional to the surface area of the droplet, while laser induced fluorescence (LIF) emits an intensity proportional to the spray volume. As a result, processing of instantaneous droplet fields using both techniques may recover an effective Sauter Mean Diameter (D32), this process is explained and demonstrated. It is well understood that collected scattered light intensity is proportional to the number of droplets as well as the size of those droplets, with increasing numbers and diameter deliver a higher intensity. Additionally, the scattering angle and position of a droplet relative to the illumination source and collection device (camera) effect the perceived local concentration. The effects of these, and other details, are demonstrated and explained in the context of the Spraying Systems Co. SprayScan™ mPT instrument as well as for general experimental setups.

**9:31AM H11.00008** 2D X-ray Radiography and 3D Computed Tomography of a Spray, DANYU LI, THEODORE J. HEINDEL, Iowa State University, EXPERIMENTAL MULTIPHASE FLOW LAB TEAM — X-ray computed tomography can provide a comprehensive three-dimensional time-average view of a spray with clear internal details. Compared with general X-ray radiography, however, it is time-consuming and the 3D reconstructions require specialized imaging tools. For axisymmetric sprays, it is possible to create a full density distribution from the 2D X-ray radiographs. In this research, broadband tube source X-rays were used to take 2D radiographs of a spray from a two-fluid coaxial nozzle. To enhance image contrast, 20% potassium iodide by mass was added to the water. Based on the circular symmetry of the spray, an Abel inversion was used to analyze the time-average radial density distribution of the spray. X-ray computed tomography was also used to quantify the internal structure and the radial density distribution of the identical spray. The results of the two were compared and showed good agreement as long as the spray is axisymmetric.

**9:44AM H11.00009** A Near-field Comparison of Flows at Similar Momentum Ratios in a Co-Flow Airblast Atomizer, THOMAS J. BURTNETT, TIMOTHY B. MORGAN, DANYU LI, JULIE K. BOTHELL, THEODORE J. HEINDEL, Iowa State University, ALBERTO ALISEDA, NATHANIAEL MACHICOANE, University of Washington, ALAN L. KASTENGREN, Argonne National Laboratory, EXPERIMENTAL MULTIPHASE FLOW LAB TEAM — Spray atomizers can be found in a wide variety of applications, from combustion systems to nasal inhalers. Capturing the dynamics of sprays and their formation in the near-field region are often challenging due to their optically dense nature. In this study, a co-flow airblast atomizer was used to disperse a stream from an inner liquid needle. Gas and liquid flow rate combinations were varied to achieve conditions with similar gas-liquid momentum ratios. The high-resolution X-ray capabilities at the Advanced Photon Source at Argonne National Laboratory were used to characterize the near-field spray formation region. Quantitative results from focused-beam X-ray measurements, such as the fluid’s equivalent path length (EPL), were determined and compared for various momentum ratios. Similar momentum ratios provided similar EPL measures in selected regions, even while the gas and liquid Reynolds numbers were varied. Regions where differences appeared for the same momentum ratio are also identified and discussed.
Turbulent environments are abundant in nature, yet they are still not completely understood. Research on particles in turbulence has focused mainly on spherical particles smaller than the viscous scale even though many organisms found in nature exceed the size of the turbulent viscous length-scale and are not spherical in shape. Sea Walnuts and other zooplankton fall into this shape and size ranges of interests. These organisms have long been considered important species in ocean ecosystems. I am interested in understanding how these organisms exchange soluble material with their environment. Using dissolving sugar particles as a proxy, I investigate the fundamental questions of how shape, surface area, and volume affect particle dissolution rates in a laboratory turbulence tank. The research thus far has shown that neither surface area nor volume alone govern the dissolution rate of dissolving particles. Determining a single governing parameter may help elucidate how organisms interact with their environment and can contribute to the design of mini robots with respect to how they sample concentration plumes in rivers, streams, oceans, and other bodies of water.

10:10AM H11.00011 Multiphase liquid entrainment measurements in high pressure piping

AMY MCCLENEY, Southwest Research Institute — A two-phase flow of natural gas and liquid heptane flowing in 3-inch and 6-inch diameter pipes pressurized up to 3,600 psig is characterized using a combination of a novel liquid sampling technique and a flow imaging technique. The results from this new measurement approach show how the phase distribution inside of the piping can be obtained as well as how the liquid entrainment fraction changes with an increase in gas and liquid velocity. In the petroleum industry, multiphase flows are encountered during natural gas production and processing. In two-phase flow scenarios, the amount and distribution of liquid in the gas stream play an important role in the selection and operation of flow measurement devices and the design of gas processing and separation equipment. The improper design of these types of equipment can negatively affect the allocation of petroleum resources. Several experimental tests have been conducted to investigate and characterize two-phase flows in pipes with low liquid levels but are based on experimental data collected at pressures less than 10 psig. This study indicates that the pressure has a significant effect in the distribution and behavior of two-phase flow mixtures, as the natural gas will dissolve in the liquid phase as the pressure increases.

10:23AM H11.00012 Optical measurements of the velocity, height and frequency of disturbance waves in saturated two-phase annular flow

THERESA B. OEHMKE, EVAN A. VARIANO, University of California, Berkeley — In two-phase annular flows, disturbance waves, i.e., large waves several times thicker than the mean thickness of the liquid film, strongly affect the heat transfer coefficient and pressure drop. In this study, an optical technique is used to simultaneously measure the instantaneous velocity and height, as well as the frequency of disturbance waves in an adiabatic two-phase annular flow of saturated R245fa. Instantaneous liquid film thickness is measured using the optical method initially proposed by Shedd and Newell (1998, https://doi.org/10.1063/1.1149232). In this method, the liquid film thickness is measured by ring patterns made by light reflected at the interface of the liquid film. A new strategy for the post-processing of the ring patterns has been developed that allows the measurement of the instantaneous velocity, height, and frequency will be presented for flows with vapor qualities between 0.63 and 0.9. Results show that disturbance waves become slower and less frequent at the high vapor qualities.

---

Monday, November 25, 2019 8:00AM - 10:36AM – Session H12 Non-Linear Dynamics: Coherent Structures II

8:00AM H12.00001 Energy cascades and the asymmetric motion of coherent structures

DOUGLAS KELLEY, JEFFREY TITHOF, University of Rochester, GERRIT HORSTMANN, University of Rochester and Helmholtz Zentrum Dresden-Rossendorf, BALACHANDRA SURI, IST Austria, HUSSAIN ALUIE, University of Rochester, MICHAEL SCHATZ, ROMAN GRIGORIEV, Georgia Tech — We present evidence for a connection between energy cascades, which transfer energy among length scales in turbulent flows, and the Lagrangian coherent structures (LCS), which describe passive scalar transport in flows. LCS come in two types, which mark regions of strongest nonlinearity in forward- and backward-time flow, respectively. But prior observations have shown a time asymmetry: in turbulent flows, and the Lagrangian coherent structures (LCS), which describe passive scalar transport in flows. LCS come in two types, which mark regions of strongest nonlinearity in forward- and backward-time flow, respectively. But prior observations have shown a time asymmetry: in real 2D flows, the Lagrangian coherent structures are highly dissipative. In this study, we find that disturbance waves become slower and less frequent at high vapor qualities.

8:13AM H12.00002 Relating 2D and 3D Lagrangian coherent structures in oceanic flows

H M ARAVIND, G. SALVADOR-VIEIRA, Northeastern University, VICKY VERMA, SUTANU SARKAR, University of California San Diego, MICHAEL ALLSHOUSE, Northeastern University — Lagrangian coherent structures (LCS) techniques reveal elliptic structures that partition the domain into minimally- and well-mixed regions (Jupiter’s Great Red Spot, Polar Vortex), and hyperbolic structures that are highly attracting/repelling material surfaces (long filaments of the Deepwater Horizon oil spill). These techniques can be applied to 3D ocean flows; however, the high computational cost of calculating 3D LCS or the lack of an accurate vertical velocity model often prevent the use of LCS techniques. In this study, we compare 2D FTLE and trajectory-clustering structures with 3D results for a high-fidelity, submesoscale simulation of an oceanic density front.

8:26AM H12.00003 Vortex boundaries as barriers to vorticity transport in two-dimensional flows\(^1\), STERGIOS KATSANOUILIS, ETH Zurich, MOHAMMAD FARAZMAND, Massachusetts Institute of Technology, MATTIA SERRA, Harvard University, GEORGE HALLER, ETH Zurich — Recent advances have revealed barriers to diffusive transport as material curves that inhibit the transport of diffusive scalars more than neighboring curves do. Extending these results, we discuss a new, fully frame-independent (objective) vortex identification method for two-dimensional flows. Our method locates vortex-core boundaries as closed material curves that inhibit the diffusion of vorticity more than other nearby material curves do. The exact solution to this calculus of variations problem provides a criterion that unites common features of empirical observations: the material and vorticity-transporting nature of observed vortex cores. We also discuss an algorithm, along with a publicly available numerical package, that enables the automatic extraction of maximally vorticity-preserving, material vortex cores from two-dimensional data sets. We conclude by demonstrating this algorithm on explicit Navier-Stokes solutions and two-dimensional turbulence simulations.

\(^1\)Turbulent Superstructures priority program, German National Science Foundation (DFG)

8:39AM H12.00004 Material barriers to the transport of momentum and vorticity\(^1\), GEORGE HALLER, ETH Zurich — Recent work has identified objective (frame-indifferent) material barriers that are the least impermeable to the diffusion of passive scalars in turbulent flows. Here we discuss the extension of these results to identify material barriers to the transport of active quantities, such as vorticity and momentum, in three-dimensional unsteady flows. Challenges in such an extension include the vectorial nature of these active quantities, as well as their dependence on the frame of reference. With these challenges addressed, we obtain a general algorithm for locating objective material barriers to active transport, which form a dynamical skeleton around possible pathways in the flow. We illustrate the results on closed-form solutions of the Navier-Stokes equations, and well as on three-dimensional numerical simulations.

\(^1\)Partially supported by the Turbulent Superstructures program of the German National Science Foundation

8:52AM H12.00005 Stochastic Lagrangian Dynamics of Vorticity in Wall-Bounded Flows: General Theory\(^2\), GREGORY EYINK, The Johns Hopkins University, AKSHAT GUPTA, Technical University of Munich, TAMER ZAKI, The Johns Hopkins University — The Lagrangian properties of vorticity for a smooth Euler solution have been extended to Navier-Stokes solutions by Constantin-Iyer (2008,2011) using a stochastic Lagrangian approach. This is best understood within the Kuz'min-Oseledeits formulation of Navier-Stokes, in terms of the “vortex-momentum” associated to a continuous distribution of infinitesimal vortex rings. This theory provides an infinite set of exact Lagrangian conservation laws for Navier-Stokes vorticity, the “stochastic Cauchy invariants”. These are preserved only backward in time, due to the irreversibility of Navier-Stokes dynamics. For wall-bounded flows, these invariants allow a complete representation of interior vorticity in terms of vorticity generated at a solid wall, as it is advected, stretched and rotated by the flow. We present a Monte Carlo method to calculate the stochastic Cauchy invariants and their statistics by solving the SDE’s for ensembles of stochastic Lagrangian particles. We test the method using a space-time database of turbulent channel-flow at \(R_e = 1000\), verifying the conservation of mean values of the stochastic Cauchy invariants. Their variances grow exponentially in time, reflecting Lagrangian chaos in the channel flow and implying large cancellations in the conserved means.

9:05AM H12.00006 Stochastic Lagrangian Dynamics of Vorticity in Wall-Bounded Flows: Turbulent Channel-Flow\(^1\), AKSHAT GUPTA, Technical University of Munich, GREGORY EYINK, TAMER ZAKI, The Johns Hopkins University — We exploit an exact stochastic Lagrangian formulation of Navier-Stokes to study vorticity dynamics in a turbulent channel-flow at \(R_e = 1000\). “Stochastic Cauchy invariants” are conserved on average backward in time along stochastic Lagrangian particle trajectories, even as individual vorticity vectors are advected, stretched and rotated. At close prior times, conservation requires delicate cancellations between vorticity contributions from particles in the interior of the flow and those which strike the wall and remain fixed there. Far back in time, interior vorticity is represented by an average over vorticity that originated entirely at the wall. As in superfluids, cross-stream transport of tangential vorticity generated at the wall is exactly related to drag. We show that the process of vortex-lifting in the buffer layer is not an abrupt lifting of discrete vortex lines but is instead distributed over 100’s of viscous times and 1000’s of wall units. Despite simple arrays of “hairpin” vortex-lines, the dynamics involves intense competition between nonlinear Lagrangian chaos that exponentially magnifies \& rotates vorticity and strong viscous destruction. We discuss the Lighthill-Morton theory of vorticity generation from this stochastic Lagrangian perspective.

9:18AM H12.00007 True topology of 3D unsteady flows with spheroidal invariant surfaces\(^1\), MICHEL SPEETJENS, SEBASTIAN CONTRERAS, HERMAN CLERCX, Eindhoven University of Technology — Scope is the response of Lagrangian flow topologies of 3D time-periodic flows consisting of spheroidal invariant surfaces (ISS) to perturbation. Such ISS have intra-surface Hamiltonian topologies comprising of islands and chaotic seas. Computational studies predict a response to perturbation dramatically different from the classical case of toroidal ISS: said islands and chaotic seas evolve into ‘tube-and-shell’ structures by ‘resonance-induced merger’ (RIM). This study provides conclusive experimental proof of RIM and advances the corresponding structures as the true topology of realistic flows with spheroidal ISS; the latter are singular entities that exist only for ideal conditions. Theoretical analysis reveals that RIM ensues from perturbed periodic lines via two possible scenarios: truncation of tubes by (i) manifolds of isolated periodic points emerging near elliptic lines or by (ii) segmentation of lines into elliptic and hyperbolic parts. This Furthermore demonstrates that RIM indeed accomplishes tube-shell merger by exposing the existence of ISS that smoothly extend from tubes into chaotic shells. These phenomena set the response to perturbation – and true topology – of flows with spheroidal ISS fundamentally apart from flows with toroidal ISS.

9:31AM H12.00008 Critical point identification in 3D velocity fields.¹, MOHAMMADREZA ZHARFA, PAUL S. KRUEGER, Southern Methodist University — Classification of flow fields involving strong vortices such as those from bluff body wakes and animal locomotion can provide important insight to their hydrodynamic behavior. Previous work has successfully classified 2D flow fields based on critical points of the velocity field and the structure of an associated weighted graph using the critical points as vertices. The present work focuses on extension of this approach to 3D flows. To this end, we have used the Gauss-Bonnet theorem to find critical points and their indices in 3D vector field, which functions similarly to the Poincare-Bendixon theorem in 2D flow fields. The approach utilizes an initial search for critical points based on local flow field direction, and the Gauss-Bonnet theorem is used to refine the location of critical points by dividing the volume integral from of the Gauss-Bonnet theorem into smaller regions. To verify this approach, we have applied this method on some flow fields generated from potential flow theory and numerical methods.

9:44AM H12.00009 Spectral reconstruction of incompressible flows and application to incomplete flow measurements, SIAVASH AMELI, SHAWN SHADDEN, UC Berkeley — A wide range of fluid flow applications are incompressible. Noise in flow measurements is the main source that violates the divergence-free condition for such flows. A variety of approaches have been proposed to filter noise and reconstruct data. Proper Orthogonal Decomposition, Dynamic Mode Decomposition, radial basis functions and smoothing kernels and spectral filtering by Fourier representation are a few examples. Yet, for many applications the necessity of an incompressible projection is important. Previously, we have presented the spectral representation of vector fields that addresses incompressibility by means of orthogonal family of solenoidal fields. The spectral representation of the fluid flow is obtained by the projection of the flow to the eigenmodes that are generated for a specific geometry and satisfy a flow boundary condition. In this talk, we discuss the optimality of the set of eigenfunctions in modal reduction and representation of incompressible flows. Also, we will present modal reconstruction of the flow to the eigenmodes that are generated for a specific geometry and satisfy a flow boundary condition. In this talk, we discuss the optimality of the set of eigenfunctions in modal reduction and representation of incompressible flows.

9:57AM H12.00010 Learning the Tangent Space of Dynamical Instabilities from Data, ANTOINE BLANCHARD, THEMISTOKLIS SAPSIS, MIT — The optimally time-dependent (OTD) modes are a set of deformable orthonormal tangent vectors that track directions of instabilities along any trajectory of a dynamical system. Traditionally, these modes are computed by a time-marching approach that involves solving multiple initial-boundary-value problems concurrently with the state equations. However, for a large class of dynamical systems, the OTD modes are known to depend “pointwise” on the state of the system on the attractor, and not on the history of the trajectory. We leverage the power of neural networks to learn this “pointwise” mapping from phase space to OTD space directly from data. The result of the learning process is a cartography of directions associated with strongest instabilities in phase space, as well as accurate estimates for the leading Lyapunov exponents.

10:10AM H12.00011 Search and Rescue at Sea Aided by Hidden Flow Structures, MATTIA SERRA, Harvard University, PRATIK SATHE, UCSB, IRINA RYPINA, ANTHONY KIRINICICH, WHOI, SHANE ROSS, Virginia Tech, PIERRE LERMUSIAUX, THOMAS PEACOCK, MIT, ARTHUR ALLEN, U.S. Coast Guard - Search and Rescue, GEORGE HALLER, E TITIN Zurich — Every year hundreds of people die at sea because of vessel and airplane accidents. Using recent mathematical results for assessing short-term material transport in unsteady flows, we uncover hidden Transient Attracting Profiles (TRAPs) in ocean-surface velocity data. Computable from a single velocity-field snapshot, TRAPs act as short-term attractors for all floating objects. We emulate SAR scenarios in three different ocean field experiments, and show that TRAPs computed from measured as well as modelled velocities attract deployed drifters and manikins emulating people fallen in water. TRAPs, which remain hidden to prior Eulerian diagnostics, thus provide critical information for hazard responses, such as SAR and oil spills, and have the potential to save life and limit environmental disasters.

10:23AM H12.00012 Turbulent Flow in the Vicinity of Retaining Walls: Conditions at the Early Stages of Local Scour Development, NASSER HEYDARI, PANAYIOTIS DIPLAS, Department of Civil and Environmental Engineering, Lehigh University, Bethlehem, PA, J. NATHAN KUTZ, Department of Applied Mathematics, University of Washington, Seattle, WA — Turbulent flow characteristics corresponding to the initial stages of local scour development are investigated in the vicinity of a retaining wall structure. Data collection is performed using a volumetric particle image velocimetry to measure the three-dimensional velocity fields. Time-averaged flow topology, turbulence statistics, and instantaneous fields are examined. Furthermore, proper orthogonal decomposition (POD) and dynamic mode decomposition (DMD) tools are applied to further understand the underlying features of the large-scale coherent structures around the obstruction. The results indicate that a horseshoe vortex (HV) system develops over the channel bank at the upstream face of the obstruction. It follows the sloping junction line towards the toe of the channel bank and then bends in the direction of the flow. It was indicated that turbulent kinetic energy (TKE) inside the HV system and bed shear stress values in the mean flow are more pronounced near the leading edge of the protrusion where the flow acceleration is the strongest. Consistently, the leading POD and DMD modes indicate that the HV captures a significant portion of the TKE content. They also confirm the aerodynamic behavior of the HV system.

Monday, November 25, 2019 8:00AM - 10:36AM – Session H13 Convection and Buoyancy-driven Flows: General 304 - Thomas Solano, Florida State University

8:00AM H13.00001 Cafe’ Latte: Spontaneous layer formation in laterally heated double diffusive convection: Numerical simulations¹, KAI LEONG CHONG, RUI YANG, University of Twente, ROBERT VERZICCO, University of Roma, DETLEF LOHSE, University of Twente — The experiments of N. Xue et al., Nat. Commun. 8, 160 (2017) have shown that the well-known layer formation in Cafe’ Latte is due to double diffusive convection, with the hot milk injected into the coffee cooling down to the side. Here we perform a corresponding numerical investigation of laterally cooled double diffusive convection where the fluid flow is driven by a horizontal temperature difference and stabilized by a vertical concentration difference. When the stabilization caused by the concentration field is too weak, the flow behaves like standard vertical convection in which there is a large-scale circulation throughout the domain. However, upon increasing stabilization, one observes the spontaneous formation of layers where there are several vertically-stacked circulations and every circulation forms a well-mixed layer. As time evolves, the two neighbouring layers can merge into one layer whenever there is strong enough flow that can break the interface in between. Finally, we analytically calculate the average initial height of the layers and find good agreement with our numerical data.

8:26AM H13.00003 Propagating fronts through convective flow fields with cooperative and antagonistic feedback1. SAIKAT MUKHERJEE, MARK PAUL, Virginia Tech — We numerically explore propagating fronts generated by an exothermic and autocatalytic reaction where the products and reactants can vary in density. We study fronts traveling horizontally in a long, shallow, and two-dimensional layer of fluid undergoing thermal convection. In the absence of heat generation by the reaction, any variation in density between the products and reactants results in a single solutally-driven convection roll that propagates with the front. In the presence of heat release by the reaction, a hotspot at the front is generated which leads to the formation of a pair of counter-rotating convection rolls that travel with the front. When the products are less dense than the reactants, the thermal and the solutal effects are cooperative. When the products are more dense than the reactants, the thermal and solutal effects are antagonistic. We study fronts with cooperative and antagonistic feedback that travel through counter-rotating convection rolls generated by Rayleigh-Bénard convection. In the presence of convection, the front and fluid dynamics exhibit oscillatory dynamics. We quantify the fluid dynamics, front velocity, and reaction length scale over a wide range of solutal and thermal driving.

8:39AM H13.00004 Conjugate Thermal Boundaries Effect On Natural Convection Flow Structures In Enclosures. TOMAS SOLANO, JUAN ORDONDEZ, KOUROSH SHOOLE, Florida State University — Buoyancy-induced flow for a heated sphere in a square enclosure coupled with external forced convection cooling of the enclosure walls is investigated numerically using an immersed boundary method and conjugate thermal boundary conditions. The external forced convection cooling, on the enclosure boundaries, is seen to significantly modify the internal convectionary flows, i.e. flow and thermal stratification depending on Rayleigh number and aspect ratio. The relation between the external Reynolds number and the internal Rayleigh number is reported in terms of streamlines, isotherms, local and average Nusselt numbers. Asymmetric and reverse flow is observed as the relation between external Reynolds and internal Rayleigh is changed. The coupling between the two modes of convection is presented as a means to control the convection pattern and vertical structures in an enclosure with heated components.

8:52AM H13.00005 Thermal convection in a rotating liquid sphere with radial gravity as a direct function of the radius.. VICTOR HUITRON, RUBEN AVILA, Facultad de Ingeniería, Universidad Nacional Autónoma de México, México City, Mexico — The thermal convection of the terrestrial planets without solid inner core, has been subject of research in the last decades. Some theories claim that at the beginning of the formation of the planets, the solid inner core was absent. This research is aimed to analyze the convective patterns and the heat transfer rate in a rotating liquid sphere by solving the non-steady, three-dimensional Navier-Stokes equations. In order to avoid the singularity at the center of the sphere, the set of equations for an incompressible fluid are formulated in a Cartesian coordinate system and solved by using the mesh-based h/p Spectral Element method. The thermal convection is driven by both a uniform internal energy source and a radial gravitational field that is directly proportional to the radius of the sphere. The effect of increasing the value of the Rayleigh Ra number and the Taylor Ta number, on the convective patterns and on the velocity, temperature and vorticity fields is presented. The local and average Nusselt numbers at the surface of the whole sphere are evaluated together with the temperature, vorticity and pressure fields. The obtained results are successfully compared with numerical solutions previously published in the literature.

9:05AM H13.00006 Diagnosis of turbulence radiation interactions in turbulent premixed flames under high-pressure and high-Ka conditions. BIFEN WU, XINYU ZHAO1, University of Connecticut — Predicting thermal radiation is crucial for prediction of wall heat transfer for aeronautical combustors. Intense turbulent fluctuations result in strong fluctuations of temperature and composition, which lead to highly nonlinear behavior in the radiative source terms that is conventionally referred to as to turbulence-radiation interactions (TRI). An a priori study of the TRI is performed using datasets from Direct Numerical Simulation (DNS) of strongly turbulent premixed n-dodecane/air flames with three Karlovitz numbers (Ka) ranging from 100 to 10000, under pressurized conditions that are relevant for engine operations. Here, a line-by-line database derived from HITEMP2010 and HITRAN2018 is employed to calculate the radiative properties of radiative species. The database is extrapolated to high-pressure conditions using the Voigt profile. The influence of various interactions in the radiative emission source term is investigated and their impact is evaluated in the context of large eddy simulations (LES) through explicit filtering with different filter sizes. Sub-grid scale TRI models of different fidelities, such as no-TRI, partially-TRI, are assessed. Different levels of soot volume fractions are also artificially introduced to investigate the influence of soot on TRI.

9:18AM H13.00007 Weakly nonlinear stability analysis on a chemotaxis system with deformed free surface. SYMPHONY CHAKRABORTY, TONY WEN-HANN SHEU, National Taiwan University, No. 1, Sec. 4, Roosevelt Road, Taipei 10617, Taiwan (R.O.C) — Chemotaxis-convection-diffusion (CCD) have significant roles in medical, industrial, and geophysical areas, that is why research effort has been performed to understand the dynamics of the bacterial motility in suspension, studies through analytical, experimental, and numerical attempts previously were only for a flat free-surface of a suspension of chemotaxis bacteria in a shallow/deep chamber. We consider now a 3D CCD flow system with a deformed free-surface to explore the nature of instability by performing detailed stability analyses. Weakly nonlinear stability analysis has been carried out to determine the relative stability of the pattern formation at the onset of instability where Rayleigh number $Ra$, is the nonlinear control parameter. Nonlinear convection terms dominated the system beyond a critical $Ra$, which also depends on the critical wavenumber $k$ and Nusselt number $Nu$, as well as other parameters. We have investigated the issue of how the critical $Ra$, in this model varies with three different sets of parameters. Using the method of multiscales, a Ginzburg-Landau equation is derived from the Lorenz model (derived under the assumption of Bossinesq approximation), the solution of which helps to quantify the energy transport through $Nu$.

9:31AM H13.00008 Linear thermal convection in an oscillatory fluid layer: A Floquet analysis of a sinusoidal, time-periodic basic flow. RUBEN AVILA, Facultad de Ingeniería, Universidad Nacional Autonoma de Mexico — The onset of thermal convection of a Boussinesq fluid confined in a plane layer with harmonic oscillation is investigated. The boundaries of the layer are parallel to the x-y plane of the Cartesian coordinate system. The temperature of the lower boundary is higher than the temperature of the upper boundary. The fluid layer oscillates around the y axis with a given amplitude and frequency. The basic velocity profile is sinusoidal and time-periodic. The flow with a linear basic temperature profile, ascends close to the hot boundary and descends close to the cold boundary. The basic harmonic is obtained numerically, and introduced as an analytical expression in the linearized equations of the vertical velocity, vorticity and temperature. The non-steady linear equations are formulated in terms of the parameters (the wave number, and the Rayleigh, Taylor and Prandtl numbers) that govern the system. The linear equations are solved (for a fluid with Prandtl number equal to 0.7) by a collocation method that is based on the Chebyshev polynomials. By using the Floquet theory, the thermal instability of the basic harmonic flow is studied. Curves of the critical values of the Rayleigh number and the wave number, as functions of the other parameters of the system are shown.

9:44AM H13.00009 Turbulent Mixing and Entrainment in a Buoyancy Driven Continuous Thermal Plume using Large-Eddy Simulations. SUDEEHER REDDY BHIMIREDDY, KIRAN BHAGANAGAR, University of Texas at San Antonio — Understanding the effects of extreme events such as wildland fires, volcanic eruptions are some of the critical issues the scientific community is facing now. For this purpose, a high-fidelity Large-Eddy Simulation has been developed to simulate thermal plumes with subcritical Froude’s number in a 4 km x 4 km x 7 km domain under idealized conditions. A fundamental fluid dynamics analysis has been performed to quantify the mean and turbulent characteristics of the thermal plumes. Additional 2-D simulations performed revealed that a well-defined head exists and travels with nearly constant velocity as long as it is attached to the plume stem. Due to intense turbulent mixing, 3-D thermal plume does not exhibit a well-defined head. To quantify the mixing and entrainment, 1st principle control volume approach based on tracking the plume interface has been used in both 2-D and 3-D cases. Using this, the interface we also study the plume ascent rate and half-widths based on both radial velocity and buoyancy profiles. Entrainment in 3-D thermal plumes is found to be significantly higher than in 2-D. The primary mechanism entraining the ambient fluid in 3-D is due to the instabilities at interface, whereas in 2-D, the centerline vorticity is found to be responsible for the mixing.

9:57AM H13.00010 Modeling of Round Buoyancy Driven Particle Clouds. ALI ALNAHIT, NIGEL KAYE, Associate Professor of Civil Engineering, ABDUL KHAN, Professor of Civil Engineering — A numerical model was developed to investigate the dynamics of round buoyancy driven particle clouds in a quiescent ambient. The developed model was validated and then applied to a range of test cases including releases of positively/negatively buoyant particles. The cloud was modeled using the standard Morton et al. (1956) entrainment assumption, and the flow field induced by the cloud was approximated as a Hill’s spherical vortex. The buoyancy of the cloud was calculated as the sum of the buoyancy contributed by all particles within the cloud. Individual particles were tracked using a particle tracking equation considering the forces acting on individual particles and the computed induced velocity field. Particle–particle interactions were modeled as both elastic and inelastic collisions. The turbulent dispersion of particles was also considered and estimated using a random walk model. The model was validated by comparing simulations with the experimental and numerical results of Wang et al. 2016. The limitations of the model were then discussed.

10:10AM H13.00011 Buoyancy distribution in a filling box segmented by a planar jet. NIGEL KAYE, Clemson University, NICHOLAS WILLIAMSON, University of Sydney — Results are presented from a theoretical and experimental investigation of the buoyancy distribution in a filling box in which the box is divided by a planar jet. The planar jet acts as a barrier that inhibits the transfer of buoyancy from the plume side to the non-plume side of the jet. Filling box theory is used to model the layer depth and total buoyancy on either side of the planar jet. Although the planar jet initially prevents the plume outflow from spreading into the non-plume side there is still some transfer of buoyancy due to entrainment of buoyant fluid into the planar jet that is then transferred to the non-plume side. The theoretical model is validated against a series of small scale salt bath experiments. The model well predicts the initial distribution of buoyancy between the plume and non-plume sides of the jet. However, the build-up of buoyancy on the plume side eventually bends the jet toward the non-plume side and the jet no longer provides a barrier. The time at which the model breaks down is well predicted by air-curtain theory. The results are discussed in the context of the potential for air curtains to inhibit smoke spread in compartment fires and potentially allowing increased evacuation times for occupants.

10:23AM H13.00012 Manipulation of Small-Scale Motions Induced by Self-Oscillating Reeds for Heat Transfer Enhancement. SOURABH JHA, ARI GLEZER, Georgia Institute of Technology — Low Reynolds (Re) number forced convection heat transport within the fin channels of air-cooled condensers are enhanced by deliberate formation of unsteady, small-scale vortical motions using aero-elastically fluttering thin-film reeds that span the channel height. These vortical motions substantially increase the local heat transfer coefficient at the channel walls and mixing between the wall thermal boundary layers and the cooler core flow. The flow mechanisms associated with production, advection and dissipation of these small-scale motions are investigated in a modular, high aspect ratio channel using micro-PIV, video imaging of the reed motion, and hot-wire anemometry. The global heat transfer enhancement is investigated in a modular heat sink prototype using temperature and pressure measurements. It is shown that the reed-induced small scale motions increase the turbulent kinetic energy of the flow even when the base flow undergoes transition to turbulence, leading to an increase in the local and global Nusselt number (Nu) that is sustained at higher Re and a minor relative increase in losses. While these losses depend primarily on the reed’s oscillation Strouhal number (St=fL/U) which is determined by the reed’s mass ratio (M*) and structural rigidity (I*) , because the global Nu depends only weakly on St, the losses associated with the presence of the reed can be strongly mitigated by reducing its St while maintaining the heat transfer enhancement.

Monday, November 25, 2019 8:00AM - 10:36AM — Session H14 Convection and Buoyancy-driven Flows: Turbulent Rayleigh-Benard
8:00AM H14.0001 Elusive transition to the ultimate regime of turbulent RBC: Dynamics of LSC in high-Ra cryogenic helium experiments1, MICHAL MACEK, PAVEL URBAN, PAVEL HANZELKA, TOM KRLK, VRA MUSILOV, The Czech Academy of Sciences, Charles University, Faculty of Mathematics and Physics — Non Oberbeck-Boussinesq (NOB) effects may increase the heat transfer efficiency of turbulent Rayleigh-Bénard convection (RBC), when the top plate temperature approaches the saturation vapor curve (SVC) even far away from the critical point of the working fluid. Our recent experimental study [1] using cryogenic He under conditions as close as possible to the Goettingen study using SF6 [2] argues that the claim of having observed the transition to Kraichnans ultimate \( Nu(Ra) \) scaling is likely due to NOB effects, and the important issue of transition to the ultimate state of RBC remains open. I will present here a detailed analysis of large-scale circulation (LSC) dynamics in the experiment [1]. I will discuss dependences of the Reynolds numbers associated with LSC circulation and sloshing and of the LSC reversal frequency on the position in the \( p-T \) diagram of \( ^4 \)He, in particular on the boundary layer asymmetry due to NOB conditions near the SVC. [1] P. Urban, P. Hanzelka, T. Krlk, M. Maccek, V. Musilov and L. Skrbek, Phys. Rev. E 99, 011101(R) (2019).

8:26AM H14.00003 Velocity and Thermal Boundary Layer Equations for Turbulent Rayleigh-Bénard Convection1, EMILY SC CHING, H.S. LEUNG, Department of Physics, The Chinese University of Hong Kong, LUKAS ZWIRNER, OLGA SHISHKINA, Max Planck Institute for Dynamics and Self-Organization — In turbulent Rayleigh-Bénard convection, the boundary layers (BLs) are non-steady with fluctuations, the time-averaged large-scale circulating velocity vanishes far away from the top and bottom plates, and the motion arises from buoyancy. There is no existing BL theory that successfully incorporates all these physical effects. We have derived a full set of BL equations for both the temperature and velocity fields from the Boussinesq equations for a two-dimensional fluid above a heated plate, accounting for all these physical effects. We use the commonly employed concepts of eddy viscosity and eddy thermal diffusivity to study fluctuations and propose a closure model to relate them to the stream function. This full set of BL equations enables us to obtain the time-averaged velocity and temperature BL profiles, in the form of similarity solutions, for general Prandtl number (\( Pr \)) in terms of two parameters \( k_1 \) and \( k_2 \) that measure the size of fluctuations. We have demonstrated that with a suitable choice of \( k_1 \) and \( k_2 \), our theoretical results are good approximations of both the time-averaged velocity and temperature profiles obtained in direct numerical simulations especially at low \( Pr \), for which theoretical results are challenging to obtain.

8:39AM H14.00004 Effects of Prandtl number in quasi-two-dimensional turbulent Rayleigh-Bnard convection1, XIAO-MING LI, JI-DONG HE, PENG HAO, SHI-DI HUANG, Department of Mechanics and Aerospace Engineering, South University of Science and Technology, Shenzhen, Guangdong 518055, China — We report an experimental study of the Prandtl (\( Pr \)) number effects on flow pattern and local temperature fluctuation in quasi-two-dimensional turbulent Rayleigh-Bénard convection. The experiments were conducted in four rectangular cells with same aspect ratio but different heights, the Rayleigh number \( Ra \) range (1e9 − 2e10) remains unchanged while \( Pr \) is varied from 11.6 to 157.4. The flow patterns visualized by the shadowgraph show that thermal plumes become more slender as \( Pr \) increases, and their organized-motion is more concentrated towards the sidewall. The mean flow strength, characterized by the Reynolds number \( Re \), becomes weaker with the increase of \( Pr \), i.e. \( Re(0.57Pr^{0.81}) \). It is further found that the temperature fluctuations in the center (\( \sigma_T/\Delta T \)) and near sidewall (\( \sigma_T/\Delta T \)) behave different, i.e. \( Pr<0.19Ra<0.28 \) and \( Pr>0.19Ra>0.20 \), respectively. This result quantitatively demonstrates that, as \( Pr \) increases, thermal plumes prefer to move along the sidewall rather than traveling through the center of the cell.

1This work was supported by the National Natural Science Foundation of China under Grant Nos. 11702128 and 91752201.

8:52AM H14.00005 Effect of slip boundary conditions on the heat flux and near-wall temperature equations in turbulent Rayleigh-Bénard convection1, XIAOZHOU HE, MAOJING HUANG, Harbin Institute of Technology(Shenzhen), YIN WANG, HONG KONG University of Science and Technology, YUN BAO, Sun Yat-Sen University — We present direct numerical simulations (DNS) of the heat transport and near-wall temperature profiles in turbulent Rayleigh-Bénard convection (RBC) with slip boundary conditions (BCs) on horizontal walls. The mean horizontal velocity on the wall is assumed as \( u_w = (b/L)(\partial u/\partial n)|_w \). Here \( L \) is the height of RBC sample, \( b \) is the slip length with \( b = 0 \) for no-slip BC and \( b \to \infty \) for free-slip BC. The simulations were for \( 0 \leq L/b \to \infty \) and the Prandtl numbers \( Pr = 4.3 \). It was found that the ratio of dimensionless heat flux, as expressed by the Nusselt number follows \( Nu/Nu_0 = 0.8 \times \tanh(100 \times b/L) + 1 \), where \( Nu_0 \) is the Nusselt number for \( b = 0 \). Considering the boundary layer fluctuations, we derived the equation \( \Theta(x) = \int_{-\infty}^{\infty}(1+2p^2q^2)^{-1}dp \) for the mean temperature profile \( \Theta(x) \) near the horizontal surface, where \( p = \Gamma(1+1/x)\Gamma(n-1/x)/\Gamma(n) \) with \( 2 \leq x \leq 3 \) depending on \( b/L \) and \( n > 1 \) for varying geometries of the convection sample.

1Supported by NSFC Grant No.11772111.

9:05AM H14.00006 A systematic investigation of the inverse cascade and flow speed scaling behavior in rapidly rotating Rayleigh-Benard convection1, MICHAEL CALKINS, University of Colorado, Boulder, STEFANO MAFFEI, University of Leeds, MITCHELL KROUSS, KEITH JULIEN, University of Colorado, Boulder — Rotating convection is a robust driving mechanism for the inverse kinetic energy cascade, which is characterized by the transfer of energy from small-scale convective motions to large-scale motions. One of the consequences of this process is the formation of so-called large-scale vortices (LSVs) that fill the entire flow domain. However, the domain of existence for these vortices and the behavior of their saturated amplitude is not well-constrained. A systematic set of simulations of the asymptotically-reduced governing equations show that: (1) the presence of LSVs is characterized by a critical small-scale Reynolds number over a wide range of Prandtl numbers; (2) the amplitude of the LSVs scales predictively with the horizontal dimensions of the flow domain; and (3) the amplitude of the LSVs saturates with increasing Rayleigh number. Furthermore, we find that LSVs are present in flow regimes not previously known to harbor them. A scaling law is developed for the convective Reynolds number as a function of Rayleigh number and Prandtl number, which can be used to predict the presence of LSVs.

1This work was funded by NSF grant EAR-1620649.
In summary, four local Nu-scalings are obtained: 1. buffer layer thickness and the ejecting velocity as large scale circulation velocity, the balance of inertia and buoyancy yields $\text{Nu}$ the similarity of the momentum and thermal boundary layer. In plume-ejecting region, after choosing the proper scale of plume scale as the intermittent boundary layer dynamics. Various strategies for improving the efficiency of statistical convergence will also be presented.

We acknowledge support by the Priority Programme SPP 1881 of the Deutsche Forschungsgemeinschaft and an award of computer time provided by the INCITE program. This research used resources of the ALCF at ANL, which is supported by the DOE under contract DE-AC02-06CH11357.

We present the dependence of the heat transport (the Nusselt number) and momentum transport (the Reynolds number) as expected, the energy transfer differs significantly between the bulk and close to the wall. At large Rayleigh numbers, the energy input into the superstructures is primarily balanced by a direct energy transfer to smaller scales in the bulk. Here, the energy transfer acts as an effective dissipation for the superstructures. However, close to the wall the energy transfer is more complex and may even drive the superstructures. Besides a characterization, these results can help to develop an effective description of turbulent superstructures in convection.

Inhomogeneous Nu distribution along horizontal plate, with four flow regimes, i.e. corner-roll, jet-impingement, wind-shearing and plume-ejecting. In corner-roll, Nu scaling follows a modified mixing zone model, with a scale correction $r \sim Ra^{-0.65}$. In jet-impingement region, a streamwise momentum similarity yields an Nu distribution: $Nu_{ji} = 0.2Ra^{1/4} \exp(-1.2(x-x_{eo})/L_{ji})$. In wind-shearing region, side wall does not affect the similarity of the momentum and thermal boundary layer. In plume-ejecting region, after choosing the proper scale of plume scale as the buffer layer thickness and the ejecting velocity as large scale circulation velocity, the balance of inertia and buoyancy yields $Nu_{pe} \sim Ra^{1/369}$. In summary, four local Nu-scalings are obtained: 1/3, 0.30, 0.262, and 0.369, and the global Nu scaling is then obtained by adding all four with multiplying them with their spatial domain sizes. This model provides an alternative interpretation for Nu-scaling transition.

10:23AM H14.00012 Near free-fall oscillatory velocities in liquid metal rotating convection. TOBIAS VOCT, HZDR, SUSANNE HORN, Coventry University, JONATHAN AURNOU, UCLA, HELMHOLTZ-ZENTRUM DRESDEN-ROSENTORF TEAM, UNIVERSITY OF CALIFORNIA, LOS ANGELES TEAM, COVENTRY UNIVERSITY TEAM — The geomagnetic field is induced by liquid metal flow inside Earths outer core as a self-excited dynamo. Buoyancy drives the liquid metal flow because the iron rich core is cooling from its primordial state through heat loss to the mantle. The rotation of the Earth and Lorentz forces alter the resulting convective flow. However, the detailed flow topology is largely unknown. Here we will investigate the effect of rotation on a low Prandtl number thermal convection by means of laboratory experiments and DNS. Therefore, we consider a rotating Rayleigh-Bénard convection setup in an upright cylindrical vessel of aspect ratio $\Gamma = D/H \approx 2$. We investigate supercriticalities in the range of $1 < \text{Ra} < 20$ and Ekman numbers $4 \times 10^{-5} \leq \nu \leq 2 \times 10^{-6}$ in liquid gallium at $Pr = 0.03$. By means of ultrasound-Doppler velocity measurements, we find that oscillatory convection generates velocities approaching the freefall velocity. Multi-modal bulk oscillations dominate the vertical velocity field over the whole range of supercriticalities investigated. Additionally, coherent mean zonal flows and time-mean helicity suggesting that these oscillatory flows can be relevant for dynamo action.

Monday, November 25, 2019 8:00AM - 10:36AM — Session H15 Turbulent Boundary Layers: Roughness and Atmospheric Turbulence

8:00AM H15.00001 Altered large-scale structures in turbulent boundary layers formed over drag-increasing riblets. RYAN NEWTON, DANIEL CHUNG, NICHOLAS HUTCHINS, University of Melbourne — Riblet drag reduction only occurs within a small, viscous-scaled riblet spacing envelope, outside of which drag is significantly increased. In this study, non-optimal, drag-increasing trapezoidal riblet surfaces, with a 30° tip angle and height of 0.5s are experimentally investigated in the regime where the viscous-scaled riblet spacing is large ($40 < s^+ < 250$). The motivation behind this is to understand the cause of the drag increase in this regime. Results indicate that riblets with a large $s^+$ provide a considerable drag penalty, which appears to asymptote to fully rough behavior as $s^+$ increases. An analysis of the turbulence close to the surface reveals that there is little evidence of either lodgment of near-wall turbulence in the riblet grooves, or of a Kelvin–Helmholtz instability above the riblet crests. This suggests that the two previously hypothesized mechanisms for the breakdown in drag reduction at $s^+ \approx 20$, do not play a role at large $s^+$. In addition, energy spectra show that the riblets greatly diminish the footprint of large-scale turbulent motions in the near-wall and logarithmic regions, questioning the presence of a typical log layer and the validity of outer-layer similarity for these cases.

8:13AM H15.00002 Scale interactions in velocity and pressure over urban-like roughness. MANUEL FERREIRA, BHARATHRAM GANAPTHISUBRAMANI, University of Southampton — An integral description of a boundary layer developing over a large-cube array is obtained using velocity data to reconstruct the underlying pressure field via 2D-TH. Coupled-statistics of the pressure forces acting on a target roughness element provide insight into the relevant mechanisms responsible for surface drag. This is complemented by conditional analysis and extended POD of the pressure field based on velocity modes to further understand the velocity-pressure interrelations. Coherent motions, at different scales, leave a strong imprint on the pressure field. Larger turbulent features dominate pressure variance, but their direct contribution to surface drag appears to be mitigated by the relative size of the roughness obstacles that are considerably smaller. Pressure waves induced by the passage of alternating high and low-momentum regions evenly affect the flow field over a wide region, coupling the forces on the windward and leeward sides of the cube which, in turn, partially cancel each other out. This suggests that uncorrelated, intermediate and small-scale pressure fluctuations are more important to the drag force variance. Large-scale structures are nonetheless significant for the role they play in modulating the small-scale pressure events in the near wall region.

8:26AM H15.00003 Post fully rough regime in turbulent pipe flow. DANIEL CRUZ, HAMIDREZA ANBARLOOEI, FABIO RAMOS, CECILIA MAGESKI, ATILA FREIRE, Federal University of Rio de Janeiro — The phenomenological model of Gioia and Chakraborty (2006) tries to relate the friction and energy spectrum in the friction layers. In this model, the momentum transfer by eddies at a specified surface above the wall shear stress. At low Reynolds numbers, the dominant eddies are in the size of the Kolmogorov length scale (Blasius regime), while at high Reynolds numbers the dominant eddies are in the size of the roughness elements (fully rough regime). The present authors recently showed that instead of a simple transition between these two extremes, there is a third regime where the effects of the wall (through attached eddies) dominate. This results in a new power-law friction regime between the Blasius and fully rough regimes. The effects of the roughness geometry on turbulence are studied experimentally in the present work. Beside the common sand-roughed surfaces, some well geometrically defined rough walls have also been examined. As expected, by increasing the Reynolds number, the fully rough regime appears for the latter type of roughness. However, a further increase in the Reynolds reveals an unexpected behavior, where friction starts to decrease again in a power-law manner (with the same trend as observed for the third regime).

8:39AM H15.00004 The influence of regular and random roughness on outer-layer similarity. MICHAEL SCHULTZ, United States Naval Academy, KRISTOFER WOMACK, Johns Hopkins University, RALPH VOLINO, United States Naval Academy, CHARLES MENEVEAU, Johns Hopkins University — An experimental investigation was carried out on rough-wall, turbulent boundary layers with regular and random roughness element arrangements. Varying planform densities of truncated cone roughness elements in square staggered patterns and random arrangements were investigated. Velocity statistics were measured via two-component laser Doppler velocimetry and stereo particle image velocimetry. Differences in the mean streamwise velocity profiles recorded over the regular arrangements were confined to within one roughness height above the roughness crests whereas the random cases exhibited significant variation across the span that persisted into the outer layer. Evidence is shown that the differences result from low momentum pathways (LMPs) and high momentum pathways (HMPs) over the random surfaces which are not observed over the regular surfaces. The LMPs and HMPs were marked by elevated and depressed Reynolds shear stress as seen by previous investigators. However, previous studies had systematic or regular surface topography which they linked to the secondary flows. The present results indicate that secondary flows may develop even in the absence of these surface characteristics.

The authors gratefully acknowledge financial support from the National Defense Science and Engineering Graduate Fellowship (K.W.), the US Office of Naval Research (M.S. and R.J.), and NSF grant CBET-1738918 (C.M.).
The form-induced velocity affects the budget of $\overline{\theta'\theta'}$, more than that of $\overline{u'u'}$.

10:10AM H15.00011 Moving horizon estimation of turbulent velocity fields in the atmospheric boundary layer using lidar measurements and large eddy simulations\(^1\), PIETER BAUWEREAUTS, JOHAN MEYERS, KU Leuven — Pulsed lidar sensors measure the line-of-sight (LOS) projected wind velocity in the atmospheric boundary layer at a range of locations along the LOS spanning several kilometres. Despite the vast amount of measurement information, the data remains sparse and unidirectional. To reconstruct a full 3D velocity field, we employ a non-linear moving horizon estimation (or 4D-Var) approach, using large-eddy simulations (LES) as a state space model. The cost function, which represents the relative probability of the state space trajectories, is comprised of two terms, the first term regularizes the optimization based on prior statistical knowledge of the velocity field fluctuations embedded in the 2-point covariance tensor of the atmospheric boundary layer. To this end, the covariance tensor is averaged offline over a sufficiently long time window, to ensure statistical convergence. The second part penalizes the difference between the LES and real observations over the time horizon. Instead of using experimental data, we use a fine-grid LES simulation as a virtual reality, creating a controlled and flexible testing environment. The methodology is demonstrated on two measurement setups, a standard plan-position indicator scanning mode and a 3D trajectory based on a Lissajous curve.

10:23AM H15.00012 Resolving near-wall particle dynamics for turbulence-induced saltation and dispersion , TAEHOON KIM, SAMUEL HAMERMESH, RUI NI, Johns Hopkins University — The Stanley-Corssin wind tunnel at Johns Hopkins University has recently been repurposed for studying sediment transport over an erodible surface. To resolve the near-wall particle dynamics, a hybrid technique that uses both the back illumination and scattering light illumination was adopted to measure the particle dynamics over a wide range of scales. In particular, it allows us to resolve particle motion across the near-wall saltation layer using our in-house particle tracking code. From this experiment, the entire time history of particle behaviors can be acquired. In this presentation, we will discuss the statistics of near-wall particle motion and its relationship with the near-wall turbulence.

Monday, November 25, 2019 8:00AM - 10:36AM – Session H16 Focus Session: Exascale Computations of Complex Turbulent Flows I

8:00AM H16.00001 Thoughts on Very Large Turbulence Simulations , PHILIPPE SPALART, Boeing Commercial Airlines — The Reynolds number in channel DNS rose by a factor of 29 since the KMM paper of 1987. The imminent step from about 10\(^{4}\) FLOPS to 10\(^{7}\) FLOPS allows a factor of about 3. If we elect to simulate the same flow. Turbulence created three challenges: its results conflict with our semi-theory of wall-bounded flows. First, even with this factor of 29, a true logarithmic layer is not found. Second, the Reynolds stresses do not have a plateau in the (near) log layer. Third, they are not independent of the flow Reynolds number at a fixed \(y^+\). In fact, all these properties are implied by classical theory and satisfied by turbulence models of conventional type. This has greatly limited the contribution of DNS to RANS models. The complaint in engineering is over smooth-body separation and reattachment. DNS of such flows at two Reynolds numbers are most desirable, but defining the same flow at different Reynolds numbers is non-trivial because of the incoming boundary layer thickness. A strategic community decision is whether simulations can be free-standing, or experimental confirmation is needed. The use of simulation data, be it physical understanding, engineering tools built with classical thinking, or tools built with Machine Learning, is challenging. For this third option, a sound definition of the mission is sorely needed. Also in high demand are non-DNS turbulence-resolving simulations, including Wall-Modeled LES and DES, as are simulations over complex geometries, say a Formula-1 car. Such simulations have had poor grids, and automatic adaptation is needed. Grid generation, even non-adaptive, could create a bottle-neck on massively-parallel machines. Grid convergence is not achieved over full geometries, even for RANS. Research can be improving SGS and Wall Models using DNS flow fields or exercising the non-DNS tools at high Reynolds numbers. It is difficult to define challenges that are clear, are attractive in an academic sense, and will illustrate the value of having 1 exaFLOPS.

8:13AM H16.00002 Tractability of LES for complex flows\(^1\), SANJEEB BOSE, KAN WANG, CHRIS IVEY, FRANK HAM, Cascade Technologies — To date, the use of large-eddy simulations (LES) has often been restricted due to relatively large computational expense (leading to intraceltably long wall clock times) and challenges in the generation of suitable grids for complex geometries. Advances in scalable mesh generation, nonlinearly stable numerical methods and wall modeling have substantially reduced the computational cost of performing LES of flows with either complex physics and/or geometries. We will discuss the computational performance and scalability of the flow solver charLES on petascale architectures and the prospects of using LES within engineering design environments where higher simulation throughput is required. The cost and fidelity will be assessed in the context of some benchmark LES, including the prediction of transonic compressor stall (NASA Rotor 37). By leveraging massively parallel petascale computing platforms, it will be shown that such calculations can be completed within hours of wall clock time.

8:26AM H16.00003 Exascale Turbulence Simulations: From Fundamental Flows to Flight Scale Aerodynamics\(^1\), KENNETH JANSEN, RICCARDO BALIN, JOHN EVANS, University of Colorado Boulder, PHILIPPE SPALART, The Boeing Corporation — This talk will provide an update on two Argonne Early Science Program (ESP) projects. The first is a Simulation ESP where prior delayed detached eddy simulations of flow control on a vertical tail at a chord Reynolds number of 325k were validated against experiments being extended to flight scale (53 times higher Reynolds number). The second is Data and Learning ESP focused on: 1) data compression, 2) turbulence modeling improvement from machine learning, 3) uncertainty quantification and multi-fidelity modeling, and 4) in situ data analytics. Progress made towards these ambitious goals will be shared as well as future plans and needed developments.

1This work is supported not only by Argonne National Labs through the aforementioned ESP projects but also by the National Science Foundation (NSF), award number CBET-1710670 and by the National Aeronautics and Space Administration (NASA), award number 80NSSC18M0147. Resources of the Argonne Leadership Computing Facility, a DOE Office of Science User Facility, and of the NASA HECC facilities were used.

8:52AM H16.00005 Toward Simulating Turbulent Wall-Bounded Flows at High Reynolds Numbers on Exascale Platforms1, RAMESH BALAKRISHNAN, Argonne National Laboratory, PAUL FISCHER, University of Illinois at Urbana-Champaign — Given that wall resolved LES (WRLES) of high Reynolds number flows will continue to be intractable on even exascale computing platforms, there is considerable effort to make hybrid RANS/LES (HRLES) methods the tool of choice for predictive simulations of high-Re separated flows. The fidelity of HRLES depends on the ability of the subgrid model to account for the effects of the filtered scales on the resolved scales, and on the numerical schemes that are used to evolve the Navier-Stokes equations. While higher-order numerical schemes, with low dissipation/dispersion errors (and higher arithmetic intensity), are commonly used for canonical flow simulations (on simpler geometries), the bulk of the high-Re flow simulations on complex geometry still employ nominally second-order accurate schemes in structured/unstructured flow solvers. Hence, there is a need for better sub-grid models that can improve the predictive capability of both the higher-order flow solvers and existing second-order accurate flow solvers, for simulating turbulent separated flows. This talk is about ongoing efforts to develop HRLES subgrid models from DNS/WRLES simulations of canonical flows over curved and sharply discontinuous surfaces and their ability to predict high-Re flows on current petascale platforms.

1This research used resources of the Argonne Leadership Computing Facility, which is a DOE Office of Science User Facility supported under Contract DE-AC02-06CH11357.

8:26AM H16.00006 Toward Simulating Turbulent Wall-Bounded Flows at High Reynolds Numbers on Exascale Platforms1, RAMESH BALAKRISHNAN, Argonne National Laboratory, PAUL FISCHER, University of Illinois at Urbana-Champaign — Given that wall resolved LES (WRLES) of high Reynolds number flows will continue to be intractable on even exascale computing platforms, there is considerable effort to make hybrid RANS/LES (HRLES) methods the tool of choice for predictive simulations of high-Re separated flows. The fidelity of HRLES depends on the ability of the subgrid model to account for the effects of the filtered scales on the resolved scales, and on the numerical schemes that are used to evolve the Navier-Stokes equations. While higher-order numerical schemes, with low dissipation/dispersion errors (and higher arithmetic intensity), are commonly used for canonical flow simulations (on simpler geometries), the bulk of the high-Re flow simulations on complex geometry still employ nominally second-order accurate schemes in structured/unstructured flow solvers. Hence, there is a need for better sub-grid models that can improve the predictive capability of both the higher-order flow solvers and existing second-order accurate flow solvers, for simulating turbulent separated flows. This talk is about ongoing efforts to develop HRLES subgrid models from DNS/WRLES simulations of canonical flows over curved and sharply discontinuous surfaces and their ability to predict high-Re flows on current petascale platforms.

9:05AM H16.00006 Wall-resolved LES of a complex turbulent flow, MUJEEB MALIK, NASA Langley Research Center, ALI UZUN, National Institute of Aerospace — Implicit, wall-resolved large eddy simulation, using a fourth-order compact difference scheme, is performed for a relatively high Reynolds number flow involving shock-induced flow separation. This is perhaps one of the most ambitious such simulations employing 24 billion grid points, pushing the boundary of flow simulations on high performance computing hardware. The particular case selected for this simulation is that of the well-known Bachalo-Johnson experiment conducted on a cylindrical body with an axisymmetric bump, which involves transonic shock-induced boundary layer separation with subsequent reattachment downstream of the bump. The Reynolds number based on the hump chord is 2.763 million. The relatively high Reynolds number of the test case makes the wall-resolved simulation very challenging, requiring billions of grid points. We will discuss the various issues and challenges encountered during the course of this research. Comparison of the simulation results is made with the available experimental measurements, with a view toward assessing the predictive capability of the simulations. Work supported by NASA’s Transformational Tools and Technologies Project.

9:18AM H16.00007 Wall-Modeled Large Eddy Simulation (WMLES) of High-Lift Aircraft1, KONRAD GOC, SANJEEB BOSE, PARVIZ MOIN, Stanford University — Wall-Modeled Large Eddy Simulations with an equilibrium wall model (WMLES) are carried out on the JAXA high-lift model at various angles of attack. The configuration features the geometric complexity of deployed slats, flaps, and associated bracketry with flow in the low Mach, high Reynolds number regime (e.g., takeoff conditions). Salient flow features arising from smooth-body and geometrically-imposed separation are captured. The lift curve slope predicted by WMLES is well-characterized near the stall flight condition. Good agreement with experimental sectional pressure measurements is obtained. Calculations that include the wind tunnel walls and half-model mount are compared to uncorrected experimental data to mitigate wind tunnel correction uncertainty. Simulations were performed using the CharLES code at core-hour costs comparable to some RANS calculations of the same configuration (Rumsey, 2018).

1Computer resources were provided through the INCITE Program of the Department of Energy and research funding through NASA and Boeing Research & Technology (BR&T).

9:31AM H16.00008 Harnessing Exascale Platforms to Predict Shock-Wave / Boundary-Layer Interaction1, JONATHAN POGGIE, Purdue University — Separated shock-wave / boundary-layer interactions occur in a broad flight regime, from transonic commercial aircraft to hypersonic space-access vehicles. These interactions tend to be intensely unsteady, with frequency content from fine-grained turbulence to low-frequency (~ 10 Hz) separation bubble breathing. The presence of this unsteadiness can cause problems with flight control and structural fatigue on aircraft. Simulation of this important phenomenon is extremely challenging because of the need to capture such a broad range of scales. Identification of the physical mechanisms underlying the unsteadiness may help guide the development of simplified models that capture the essential features of the interactions. To this end, our research group has been investigating separated compression ramp flows, and studied their selective response to disturbances in the incoming turbulent boundary layer. In implicit large-eddy simulations, conditional averaging identified a perturbation velocity profile associated with separation motion, and forcing in the upstream boundary layer with this particular form was found to drive large-scale separation unsteadiness downstream.

1This work has been supported by a DoE INCITE Award and AFOSR Grant FA9550-17-1-0153.
9:44AM H16.00009 Shock-induced transition and heating in hypersonic boundary layers$^1$, LIN FU, MICHAEL KARP, Center for Turbulence Research, Stanford University, Stanford CA 94305. SANJEEB T. BOSE, Cascade Technologies Inc., Palo Alto, CA 94303. PARVIZ MOIN, JAVIER URZAY, Center for Turbulence Research, Stanford University, Stanford CA 94305 — The interaction of an incident shock wave with a Mach-6 undisturbed laminar boundary layer is addressed using DNS and equilibrium wall-modeled LES (WMLES). The wall temperature is cold compared to the free-stream stagnation temperature, such that the mean temperature profile develops a peak near the wall due to viscous heating. The consequences of the interaction are that the boundary layer transitions to turbulence downstream of the shock impingement point, and that transition causes a localized significant increase in the Stanton number and skin-friction coefficient. The peak thermomechanical load increases approximately linearly with the incidence angle. WMLES prompts transition and peak heating, delays separation, and shortens the separation bubble. WMLES provides predictions of DNS peak loads within 10% at 150 times lower computational cost. In the fully-turbulent boundary layer, WMLES agrees well with DNS for the Reynolds-analogy factor (Chi and Spalding, 1966), the mean velocity and temperature profiles, including the temperature peak, and the temperature/velocity correlations.

9:57AM H16.00010 Large-Eddy Simulations of turbomachinery flows$^1$, KOEN HILLEWAERT, Université de Liège, MICHEL RASQUIN, THOMAS TOULORGE, Cenaeo — Argo is developed for scale-resolving simulations in turbomachinery in view of generating reference data for RANS models as well as the prediction of off-design performance. Based on the Discontinuous Galerkin Method, low dispersion and dissipation commensurate with DNS and LES is maintained on an unstructured mesh. Recently, work is ongoing on wall modeling in view of full machine computations. The development of turbulence models in turbomachinery is hindered by the lack of detailed reference data, as usually only experimental data are available. Due to the continuous increase in computational power, it has become possible to generate detailed numerical databases in fully controlled conditions for industrially relevant conditions. The generation and exploitation of such data sets is the aim of the European project HiFiTurb. This contribution focuses on a variant of the axisymmetric transonic bump of Bacchalo and Johnson, storing all of the terms relevant to RANS, as well as time-resolved data in the boundary layer in view of improving modeling for shock-boundary layer interaction conditions.

$^1$We gratefully acknowledge the allocation by the Argonne Leadership Computing Facility in the INCITE 2019 program, as well those granted on the Tier-1 supercomputer of the Fédération Wallonie-Bruxelles, infrastructure funded by the Walloon Region under the grant agreement n1117545. Cenaeo also benefits from financing through the European union research project HiFiTurb.

10:10AM H16.00011 Large-Eddy Simulations of turbomachinery flows: from wall-resolved academic configurations to wall-modeled industrial geometries, , FLORENT DUCHAINE, LUIS SEGUI, JEROME DE LABORDERIE, NICOLAS ODIER, JEROME DOMBARD, LAURENT GICQUEL, Cercacs, CFD TEAM — LES has been shown to be a promising tool to tackle turbomachinery challenges induced by high Reynolds and Mach numbers and complex flow physics. The CPU cost is however identified as the reason why existing LES of turbomachinery flows concern simplified configurations. CERFACS has extended the capability of the reactive LES solver AVBP for turbomachinery applications. The developments and validations have concerned the application of accurate boundary conditions at inlets and outlets as well as the numerical treatment of the rotor/stator interface compliant with LES requirements. After a brief description of the flow solver, the presentation will focus on the results and insights obtained on two configurations. The first one is the high-pressure turbine cascade LS89 for which the MUR239 operating point is still today a challenge to simulate accurately. To address this academic aerothermal case, a wall-resolved approach is used with a high-order numerical scheme. The second configuration of interest is the 3.5 stages high-pressure axial compressor CREATE. This simulation, corresponding to one of the first wall-modeled LES of such a complex machine, has shown very promising results by comparison with experimental data.

10:23AM H16.00012 Challenges and progress in adaptation of RANS models for Scale Resolving Simulations (SRS) of Turbulence , PEDRAM TAZRAEI, Mechanical Engineering, Texas AM University, SHARATH GIRIMAJI, Ocean Engineering and Aerospace Engineering, Texas AM University — Even with the advent of exascale computing, many complex turbulent flows require some degree of modeling to enable predictive calculations of real-life applications. Scale resolving simulations (SRS) capable of yielding the best possible results at various and varying degrees of resolution are ideally suited for these computations. In general, SRS models can be broadly classified into zonal and bridging methods depending on the manner in which scale resolution is achieved. While the need for SRS approach is compelling, there is no clear consensus on closure model development thus far. In this presentation, we present a formal framework for adapting well-tested RANS (Reynolds-Averaged Navier-Stokes) models for SRS sub-grid stress computations. Various challenges such as commutation error, appropriate fixed-point behavior, near-wall closures are identified. Reasonably rigorous theoretical techniques to address the above issues in SRS modeling context are proposed. Asymptotic approach of SRS toward DNS (direct numerical simulations) in the limit of cut-off length scale approaching Kolmogorov length scale is also examined.

Monday, November 25, 2019 8:00AM - 10:36AM —
Session H17 Minisymposium: Machine Learning in Fluid Mechanics 4c4 - Jeff Eldredge, University of California, Los Angeles

8:00AM H17.00001 Opportunities for Machine Learning in Fluid Mechanics$^1$, MICHAEL BRENNER, Harvard University and Google Research — There are tremendous opportunities to use recent advances in machine learning and artificial intelligence to advance fluid mechanics as a discipline. This talk will give an overview of these opportunities, including (i) making scientific discoveries, such as the discovery novel flow phenomena; (ii) defining new representation of dynamical flows that make numerical solvers more efficient; (iii) the design of novel methods for experimental imaging and characterization; and (iv) development of novel coarse-grained solvers for the Navier Stokes equations. I will summarize the advances in Machine Learning that have made these opportunities possible and include some recent examples from our own work.

$^1$National Science Foundation and Simons Foundation
8:26AM H17.00002 Interpretable and Generalizable Machine Learning for Fluid Mechanics1, STEVEN BRUNTON, University of Washington — Many tasks in fluid mechanics, such as design optimization and control, are challenging because fluids are nonlinear and exhibit a large range of scales in both space and time. This range of scales necessitates exceedingly high-dimensional measurements and computational discretization to resolve all relevant features, resulting in vast data sets and time-intensive computations. Indeed, fluid dynamics is one of the original big data fields, and many high-performance computing architectures, experimental measurement techniques, and advanced data processing and visualization algorithms were driven by decades of research in fluid mechanics. Machine learning constitutes a growing set of powerful techniques to extract patterns and build models from this data, complementing the existing theoretical, numerical, and experimental efforts in fluid mechanics. In this talk, we will explore current goals and opportunities for machine learning in fluid mechanics, and we will highlight a number of recent technical advances. Because fluid dynamics is central to transportation, health, and defense systems, we will emphasize the importance of machine learning solutions that are interpretable, explainable, generalizable, and that respect known physics.

1Army Research Office PECASE (W911NF-19-1-0045; Program Manager: Dr. Matthew Munson), and Air Force Office of Scientific Research YIP (FA9550-18-1-0200; Program Manager: Dr. Gregg Abate)

8:52AM H17.00003 Machine learning for Predictive Turbulence Modeling : A Cautiously Optimistic Perspective1, KARTHIK DURAIYAM, University of Michigan — Machine learning has shown promise in describing, reconstructing or even predicting properties of a given system, given large amounts of relevant data. This talk focuses on how one can construct data-augmented models for turbulent flows that can learn from different systems, and transfer this modeling knowledge to make predictions in other systems in a non-parametric context. This defines a paradigm of transfer learning in the sense that the learning should target global rules - rather than problem-specific information - that is common to a class of systems that share similar physics. In the limit of finite (big or small) data, this requires the enforcement of a variety of physical, physics-inspired and empirically-known constraints. We embed learning within a context within PDE models in an integrating fashion, thus enforcing consistency between the learning and model construction. Examples of the enforcement of hard and soft constraints will be provided. These hybrid models are trained across different systems that are representative of the underlying model discrepancy, yielding predictions on unseen problems with quantified error bounds. Algorithmic, physical and data-related challenges will be discussed toward the end of achieving truly robust and generalizable models.

1Supported by the National Science Foundation & the Office of Naval Research

9:18AM H17.00004 Deep Reinforcement Learning for Flow Control1, PETROS KOUMOUT-SAKOS, ETH Zurich — Reinforcement Learning (RL) is a mathematical framework for problem solving that implies goal-directed interactions of an agent with its environment. The agent has a repertoire of actions, perceives states and learns a policy from its experiences in the large of rewards. Deep recurrent neural networks can be used to encode the state-action policy of the agent and effective training implies a selective choice of experiences. RL does not require a model of the dynamics, such as a Markov transition model, and relies instead on repeated interactions of the agent with the environment. I consider that this approximation makes it highly suitable for complex problems in fluid dynamics, albeit, presently, only when significant computing power or experimental automation is possible. Deep RL has been very successful in games (from backgammon to video games and the game of Go) and robotics, but remains rather unexplored in fluid mechanics. I hope to illustrate some of the strengths and limitations of Deep RL for flow control using simulations of perching and gliding bodies as well collective fish swimming.

1European Research Council Advanced Investigator Award 341117, Swiss National Science Foundation, Swiss National Supercomputing Centre (CSCS)

9:44AM H17.00005 Classifying Flows using Neural Networks EVA KANSO1, University of Southern California — Swimming organisms and robotic vehicles create long-lived flow disturbances that can in principle be detected and even exploited for tracking and navigation. Experimental evidence suggests that many aquatic organisms, from mate seekers to hungry predators, respond to specific hydrodynamic cues created by their respective preys. However, the exact features that make these flows distinguishable and the sensory measurements and layouts that are needed to detect them remain elusive. Here, we consider the inverse problem of classifying flow patterns from local sensory measurements. Specifically, we train neural networks to classify flow patterns by relying on flow sensors that measure a time history of the local flow signal at the sensor location. We systematically investigate the network performance for distinct types of sensory measurements: vorticity, flow velocities parallel and transverse to the direction of flow propagation, and flow speed. We show that the networks trained using transverse velocity outperform other networks, even when subjected to aggressive data corruption. We then train the network to classify flow patterns from instantaneous (one time) measurements, using a spatially-distributed array of sensors. The networks based on the spatially-distributed sensory arrays exhibit remarkable accuracy in flow classification, even when only a handful of sensors are active. We conclude by commenting on the advantages and limitations of these models for flow detection and classification, and we discuss how these results lay the groundwork for developing combined data-driven and physics-based models for flow sensing using distributed sensory arrays.

10:00AM H17.00006 Differentiable Fluid Simulations for Deep Learning NILS THURECK, Technical University of Munich — In this talk I will focus on the possibilities that arise from recent advances in the area of deep learning for accelerating and improving physics simulations. In this context, the Navier-Stokes equations represent an interesting and challenging advection-diffusion PDE that poses a variety of challenges for deep learning methods. In particular, I will focus on highlighting how differentiable fluid solvers can guide deep learning processes, and support finding desirable solutions. The existing numerical methods for efficient solvers can be leveraged within learning tasks to provide crucial information in the form of reliable gradients to update the weights of a neural networks. Interestingly, it turns out to be beneficial to combine supervised and unsupervised approaches. The former poses a much simpler learning task by providing explicit reference data that is typically pre-computed. Unsupervised learning on the other hand can provide gradients for a larger space of states that are only encountered during training runs. Here, differentiable solvers are particularly powerful to, e.g., provide neural networks with feedback about how inferred solutions influence the long-term behavior of a physical model. I will demonstrate this concept with several example solutions of coupled interactions of fluids and physical systems. Learnt solvers not only represents a valid physical system, but also an end-to-end training process for the field of physics-based deep learning. I will conclude by discussing current limitations and by giving an outlook about promising future directions.
8:00AM H18.00001 Optimum heart rate for brain-heart hemodynamic coupling and its clinical relevance for neurodegenerative diseases1, ARIAN AGHILINEJAD, FAISAL AMLANI, Department of Aerospace and Mechanical Engineering, University of Southern California, Los Angeles, CA, USA, KEVIN KING, Huntington Medical Research Institutes, Advanced Imaging Center, Pasadena, CA, USA, NIEMA PAHLEVAN, Department of Aerospace and Mechanical Engineering, University of Southern California, Los Angeles, CA, USA — Neurodegenerative diseases such as Alzheimer’s dementia have reached an epidemic proportion with a significant impact on public health. Disproportionate age-related stiffening of the aorta compared with the carotid arteries is theorized to reduce the protective impedance mismatch at the aorta-carotid interface and affect the regulation of cerebral hemodynamics. Recent clinical data has indicated the existence of a potential link between arterial stiffening, as measured by arch pulse wave velocity (PWV), and Alzheimer’s disease. In this study, we used an energy-based analysis of hemodynamic waves to quantify the effect of aortic arch stiffening on pulsatile hemodynamic transmission to cerebral vasculature. A one-dimensional blood flow model of the human vascular network was used to simulate pressure and flow wave propagations in the systemic circulation. Our results show there exists an optimum wave condition—occurring near normal human heart rates—that creates an optimum hemodynamic state for heart-brain coupling and minimizes pulsatile energy transmission to the brain. This is clinically important since excessive pulsatile energy transmission to microvasculature causes end-organ damage that may promote progression of neurodegenerative disease such as Alzheimer’s dementia.

8:13AM H18.00002 Modelling Direct Brain Cooling for Acute Ischaemic Stroke with the Vascular-Porous Model 1, LUKE FULFORD, Institute for Multiscale Thermofluids, School of Engineering, University of Edinburgh, IAN MARSHALL, PETER ANDREWS, Centre for Clinical Brain Sciences, University of Edinburgh, PRASHANT VALLURI, Institute for Multiscale Thermofluids, School of Engineering, University of Edinburgh — Ischaemic stroke is a major cause of death and disability in the world, occurring when a blockage forms in an artery supplying the brain, preventing blood from accessing part of the brain and causing a cascade of events that ultimately cause the death of tissue in the ischaemic region. Reducing the temperature of this tissue has been shown to be beneficial in increasing the treatment window and improving outcomes. Previous modelling studies with vastly idealised geometry have highlighted difficulties in reducing temperatures within the brain using non-invasive means. However by using a model with 1-dimensional vasculature embedded in a 3-dimensional porous tissue, the geometry of the brain and the ischaemic region can be accurately captured. In this work, we simulate a stroke by obstructing a selected vessel in the arterial tree, allowing for varying degrees of severity. By seeking solutions to the mass, momentum and energy equations, we demonstrate that cooling via the scalp has the potential to provide a useful reduction, around 0.5°C, in temperature within the affected area of the brain. The degree of cooling achievable is dependent on the location of the stroke.

8:26AM H18.00003 Flow in Porous Media as a Model for Intramural Periarterial Drainage from the Brain.1, KETAKI JOSHI, Department of Mechanical Engineering, State University of New York at Binghamton, USA, J. DAVID SCHAEFFER, Institute for Justice and Well-Being, State University of New York at Binghamton, USA, PAUL CHIAROT, PETER HUANG, Department of Mechanical Engineering, State University of New York at Binghamton, USA — Accumulation of beta-amyloid proteins in the vasculature of the brain is a characteristic of Alzheimer’s disease. One of the pathways to clear these proteins out of the brain is through intramural periarterial drainage (IPAD) along artery walls. There is evidence that the direction of this flow is opposite to that of the arterial blood flow. The periarterial space where IPAD takes place is mostly made up of smooth muscle cells and extracellular matrix. Deformation of the arterial wall boundaries are theorized to drive IPAD. In our earlier work, we reported on a hydrodynamic mechanism for reverse flow through the artery wall that was driven by forward propagating and reflected waves along the boundaries of an open conduit. In our current work, we have expanded our model by incorporating porous media inside the flow channel. We analyzed images of artery deformations in the brains of anesthetized mice provided by Cornell University (N. Nishimura). The quantified boundary deformations of the cerebral arteries are used in numerical simulations to predict the magnitude of the induced IPAD through the porous periarterial space. The role of geometry (i.e. porosity) and permeability on the fluid transport is determined.

1This project is funded by the National Institute on Aging (NIA/NIH).

8:39AM H18.00004 Computational Study of Hemodynamic Nature in Patient-Specific Cerebrovasculature with Lenticulostriate Artery under ICA Stenosis Conditions, TAEHAK KANG, Department of Mechanical Engineering, Chung Ang University, DEBANJAN MUKHERJEE, Department of Mechanical Engineering, University of Colorado Boulder, JEONG-MIN KIM, KWANG-YEOL PARK, Department of Neurology, College of Medicine, Chung Ang University, JAYOUNG RYU, Department of Mechanical Engineering, Chung Ang University — Lenticulostriate arteries play important role in cerebral circulation, especially in basal ganglia region. Deeper understanding of hemodynamic nature of LSA would grant more effective surgical or endovascular treatments. This is the first study to investigate hemodynamic changes in small cerebral artery, namely lenticulostriate artery (LSA), coupled with complete three-dimensional cerebral vasculature under carotid (ICA) stenosis conditions. For patient-specific study, patient CTA data with complete cerebral anatomy is obtained from STOP Stroke database, and computational reconstruction is carried out using open-source package, SimVascular. Petrov-Galerkin formulation is used to solve the fluid domain with pulsatile inflow and lumped three-element Windkessel outlet conditions. NASCET-based stenosis cases are applied to internal carotid artery for all patient-specific models, and their three-dimensional hemodynamic structure is visualized for comparison. We present the results in key hemodynamic properties and indexes such as VFR, MAP, and OSI. As a result, significant hemodynamic changes are shown in LSA and its cerebrovasculature under progressive ICA stenosis conditions.

8:52AM H18.00005 Cerebral Vascular Super Resolution Imaging and Blood Flow Measurement Using Ultrasound Enhanced Particle Tracking Velocimetry, ZENG ZHANG, JOSEPH KATZ, The Johns Hopkins University, MISUN HWANG, Childrens Hospital of Philadelphia, TODD KILBACH, Children’s Hospital of Philadelphia, PERELMAN School of Medicine, University of Pennsylvania — Hypoxic ischemic encephalopathy is a major cause of neonatal death. It is usually initiated with ischemia and hypoxia followed by blood reperfusion leading to brain damage. While conventional MRI gives hemodynamic information, it cannot be used for cerebral histology, which is vital for understanding the mechanism of reperfusion, and developing appropriate therapies. Therefore, contrast enhanced ultrasound particle tracking velocimetry (echo-PTV) is utilized to generate maps of the cerebral vasculature and blood flow velocity simultaneously. The microbubbles are injected intravenously, and the raw ultrasound images are collected using clinical systems. Blind deconvolution, local background removal, and modified histogram equalization are applied to enhance the image and map the bubble spatial distribution. Subsequently, particle tracking is initiated using cross-correlation and updated with a Kalman filter to calculate the velocity field. The microvascular map is generated by a superposition of the bubble trajectories that can be tracked for over 5 frames. The larger vessels are represented by integrating the enhanced images over the acquisition time. Results show 27% and 48% decrease in blood velocity and micro-vessels number with flow, respectively, 3 hours after ischemia.
9:05AM  H18.00006 Hemodynamics of cerebral aneurysms as cavity flow on a curved vessel. Effect of inertia, curvature, pulsatility and treatment with flow diverting stents

FANETTE CHASSAGNE, MICHAEL C. BARBOUR, VENKAT K. CHIVUKULA, LAUREL M. MARSH, MICHAEL R. LEVITT, ALBERTO ALISEDA, University of Washington, Seattle, WA, USA — Flow in cerebral aneurysms can be described as flow in a cavity on a curved vessel, with the effects of inertia, curvature and pulsatility providing the conditions under which flow separates on the leading edge of the cavity and recirculate inside the sac against the parent vessel flow, for part or all of the cardiac cycle. This strong coherent vortex in the aneurysm can provide a quasi-dissipative metric to explain the persistence of aneurysmal flow after treatment with flow diverting stents (FDS). These high porosity meshes lower the flowrate into the sac promoting the formation of a thrombus. The aim of this study is to investigate the flow pre- and post-treatment with FDS, to understand its variation with flow conditions and aneurysm geometry. Flow inside cerebral aneurysm phantoms with varying parent vessel curvature, neck size and sac aspect ratio is measured with PIV. The hemodynamics in the sac pre- and post FDS treatment are characterized for different waveforms. The results show parent vessel curvature and Dean number decreases the effect of the FDS treatment. This is due to a combination of changes in parent vessel hemodynamics at the aneurysm leading edge combined with the parent vessel curvature impact on stent porosity.

9:18AM  H18.00007 Coils vs stents: CFD investigation of the mechanisms of healing for two endovascular therapies in cerebral aneurysms

MICHAEL BARBOUR, LAUREL MARSH, Univ of Washington, FANETTE CHASSAGNE, University of Washington, VENKAT KESHAV CHIVUKULA, Univ of Washington, CORY KELLY, SAM LEVY, MICHAEL LEVITT, LOUIS KIM, Univ of Washington Medical Center, ALBERTO ALISEDA, Univ of Washington — Cerebral aneurysm treatment seeks to avoid the risk of rupture by excluding the aneurysmal sac from the circulation. Coiling and stenting are two forms of minimally invasive endovascular treatment that, while increasingly popular, present a non-negligible risk of incomplete embolization of the aneurysm. The placement of flow-diverting stents (FDS) or coils leads to aggregation of activated platelet and thrombus formation. A stable thrombus that fully occludes the aneurysm marks a successful treatment as it excludes the aneurysmal sac from hemodynamic stresses and minimizes the risk of rupture. There is currently no accurate method to predict the outcome of either endovascular therapy. We present in silico studies that show the hemodynamics changes, pre- to post-treatment, for both forms of treatment trend in opposite directions. We consider the treatment types separately to find certain changes in Eulerian variables are statistically different between the successful and unsuccessful treatments. The successfully coiled aneurysm cases were marked by a higher overall increase in the neck plane shear than the failed cases. While one of the most significant metrics for predicting a successful FDS treatment is the change in flowrate entering the aneurysm during systole.

9:31AM  H18.00008 Coils vs stents: Lagrangian-tracking investigation of the mechanisms of healing for endovascular therapies in cerebral aneurysms

MICHAEL MARSH, MICHAEL BARBOUR, FANETTE CHASSAGNE, VENKAT KESHAV CHIVUKULA, University of Washington, CORY KELLY, Univ of Washington Medical Center, SAM LEVY, University of Washington Medical Center, Stroke and Applied Neuroscience Center, MICHEAL LEVITT, LOUIS KIM, Univ of Washington — In this study we investigate the stability of aneurysm flow post-treatment with coils and stents by using a Lagrangian tracking strategy. The flowfield at the leading edge of each aneurysm is measured with particle image velocimetry (PIV) after creating a carotid bifurcation phantom and testing endovascularly treated cerebral aneurysms by means of Lagrangian tracking of platelets in CFD simulations of blood flow in patient-specific models. Flow-diverting stents (FDS) or coils can lead to aggregation of activated platelets and formation of a stable thrombus that fully occludes the aneurysm. However, there is currently no accurate method to predict the outcome of such endovascular therapy. We propose a series of Lagrangian metrics, based on trajectories of tracer particles introduced in the intracerebral vasculature, to understand the hemodynamics conditions that lead to stable thrombus formation as opposed to conditions that lead to incomplete embolization. We consider the two forms of therapies separately, using platelet residence time and shear history to complement Eulerian metrics that have traditionally been used to understand hemodynamics in intracranial aneurysms: Wall Shear Stress, WSS gradient, flow rate through the neck. We develop accurate predictors of outcomes for each endovascular treatment, using a large population of >50 patients to validate them. Your abstract body.

9:44AM  H18.00009 Difference in Hemodynamic Parameters Between Cerebral Aneurysms Models with Truncated Parent Arteries and with Parent Arteries Extending to the Carotid Siphon

YUYA UCHIYAMA, Tokyo University of Science, HIROYUKI TAKAO, The Jikei University of Medicine, SOICHIRO FUJIMURA, HIROSHI OHNO, Tokyo University of Science, FELICITAS DETMER, SARA HADAD, SETAREH SALIMI, FERNANDO MUT, George Mason University, KOJI FUKUDOME, Tokyo University of Science, JUAN CEBRAL, George Mason University, YUICHI MURAYAMA, The Jikei University of Medicine, MAKOTO YAMAMOTO, Tokyo University of Science — Recently, CFD simulations are used to study cerebral aneurysm pathologies. In the human anterior circulation, the internal carotid artery (ICA) has a particular bent section called carotid siphon. However, vessels distal and proximal of aneurysms are often truncated to perform simulations although they can have an effect on blood flow behavior. In this study, we compared hemodynamic parameters in models with and without the siphon. We selected 21 aneurysms from in vivo data using CFD. For each aneurysm (longer model) and the corresponding truncated model, we performed pulsatile blood flow simulations in all the cases, and then calculated and compared 20 typical aneurysm hemodynamic parameters in each model. Results showed that some hemodynamic parameters were different between the two models. Particularly, WSS was on average 60.6% smaller in shorter models compared to longer models. In conclusion, the inclusion of the carotid siphon to the model is important to represent the hemodynamic environment within the aneurysm.

9:57AM  H18.00010 Quantifying unstable flows in sidewall aneurysms at internal carotid aneurysms

TRUNG LE, North Dakota State University, ELIZABETH EIDENSCHINK, ALEXANDER DROFA, Sanford Health — Complex, unstable flow has been linked to aneurysm growth and rupture. Our previous works (Le et al., J. Biomech. Engr., 2010 and Le et al., Annals Biomedical Eng., 2013) have shown a possible transition from the stable mode (cavity) to the unstable mode (vortex ring). We have proposed the use of a novel index called the Enstrophy Number to characterize this transition (Le et al., 2013). However, the quantification of such a transition is lacking. Currently, there has been no efforts in quantifying unstable flows in intracranial aneurysms, which is essential in stratifying not rupture risks, but also to guide clinical management. In this work, the aneurysm geometries from six patients at Sanford Health, North Dakota are reconstructed from Magnetic Resonance Angiogram and Digital Subtraction Angiogram data. Using our in-house CFD code (Virtual Flow Simulator), high-resolution flow data is obtained. In this work, we propose the use of enstrophy mapping as a potential index to stratify aneurysm flows. We show that this type of mapping is able to differentiate stable from unstable modes in patient-specific anatomic. We also provide evidence on the link of Aneurysm Number and enstrophy mapping.

**10:23AM H18.00012 Patient-Specific Computational Modeling of Cerebrovascular AVM-related Aneurysms**

Kimberly A. Stevens, School of Mechanical Engineering, Purdue University; Aaron A. Cohen-Gadol, Goodman Campbell Brain and Spine, Department of Neurological Surgery, Indiana University School of Medicine; Ivan C. Christov, School of Mechanical Engineering, Purdue University; Vitaliy L. Rayz, Weldon School of Biomedical Engineering, Purdue University

An arteriovenous malformation (AVM) is a pathological condition where an abnormal tangle of vessels connects arteries to veins, bypassing the capillary bed. The decreased flow resistance can lead to increased flow in the vessels feeding the AVM, thought to be responsible for the pathogenesis of flow-related aneurysms. To investigate the relationship between AVMs and flow-related aneurysms, we created image-based computational fluid dynamic models of five flow-related cerebral aneurysms coupled with reduced-order lumped-parameter network models representing the AVMs. Vascular geometries for computational models are generated from CT data obtained from IU School of Medicine, and the blood flow within the geometry is computed using an open-source modeling platform, SimVascular. Once created, the model boundary conditions are modified to simulate AVM treatment and predict postoperative flow conditions. Calculated hemodynamic parameters known to influence arterial wall remodeling and intra-luminal thrombus deposition, such as the wall shear stress and oscillatory shear index, are compared between pre- and post-operative flow scenarios. Results indicate that hyperdynamic flow upstream of the AVM leads to elevated wall shear stress, which can be mitigated following AVM treatment.

The research was funded in part by the Lillian Gilbreth Postdoctoral Fellowship.

**Session H19 CFD: Advanced Turbulence Simulations**

Krishnan Mahesh, University of Minnesota, Twin Cities

**8:00AM H19.00001 Turbulent channel flow at \( R e_x = 10000 \)**

Sergio Hoyas, Universitat Politècnica de Valencia; Martin Oberlack, Stefanie Kraheberger, TU Darmstadt; Francisco Alcántara-Avilá, Universitat Politècnica de Valencia

A new simulation of a turbulent channel flow was conducted up to the limit of \( R e_x = 10000 \). The domain size is \( 2\pi h \times 2h \times \pi h \). This domain is thought to be large enough to accurately compute one point statistics of the flow. The simulation has been carried out on 2048 SuperMUC phase II cores, at a mesh of \((6144, 2101, 6144) \approx 8 \times 10^{10} \) grid points. A database with approximately 100 TB has already been created, which will be analyzed further at a later stage. As it was expected, a long logarithmic layer exists with \( k \approx 0.40 \) and extending from \( y^+ \approx 70 \) to \( y^+ \approx 2000 \). The first maximum of the indicator function is not growing anymore and remains constant. A first analysis of the intensities shows that the near wall peaks of \( u' \) and \( w' \) are still growing with \( R e_x \). The possible secondary maximum of \( u' \) is barely present. New scaling laws of \( U' \) and \( u' \) based on symmetry theory will be also shown.

**8:13AM H19.00002 Wall-resolved LES and RANS/LES hybrid analyses in turbulent heat exchanger with modified oblique wavy walls**

Kenichi Morimoto, Shu-Qun Jin, Junyu Chen, The University of Tokyo

High-performance turbulent heat exchangers play a key role in diversified energy systems/devices. In our recent work, double-pipe turbulent heat exchangers with V-shaped oblique wavy walls, with which the ratio of the heat transfer to the pressure loss is much larger than that for conventional techniques, have been proposed. The present study aims to clarify the detailed mechanism of the turbulent heat transfer enhancement, and to explore a practical numerical approach to deal with turbulence anisotropy and unsteady flow separation at high Reynolds number condition. Here we perform wall-resolved large eddy simulations based on dynamic sigma model in which a dynamic procedure is originally applied to both the velocity and thermal fields. Also we perform improved delayed detached eddy simulation (IDDES) with k-ε SST model as a near-wall model. It is shown that, with the present wall undulations, large-scale vortical structures are embedded in a steady manner inside the turbulent boundary layer, leading to remarkable enhancement of the heat transfer performance. The global and local quantities as well as wall shear stress and local wall heat flux are compared between RANS, LES and hybrid approaches. The feasibility of RANS/LES hybrid approach is explored for further shape-optimization study.

**8:26AM H19.00003 Learning about High Schmidt scalar mixing in turbulent round jets from 3D periodic box simulations**

Guillaume Blanquart, Kyupaeeck Jeff Rah, California Institute of Technology

Jet-centerline (JC) forcing technique was developed to create velocity and scalar fields of turbulent round jets in triply periodic box. This forcing method is here utilized to simulate high Schmidt number passive scalars mixing. A series of DNS have been performed to investigate the scalar field statistics of turbulent round jets with Schmidt number \( 10^4 \). This forcing method is here utilized to simulate high Schmidt number passive scalars mixing. A series of DNS have been performed to investigate the scalar field statistics of turbulent round jets. The domain size is \( 8 \times \pi h \) \times \( 8 \times \pi h \) \times \( 8 \times \pi h \). The first maximum of the indicator function is not growing anymore and remains constant. A first analysis of the intensities shows that the near wall peaks of \( u' \) and \( w' \) are still growing with \( R e_x \). The possible secondary maximum of \( u' \) is barely present. New scaling laws of \( U' \) and \( u' \) based on symmetry theory will be also shown.
8:39AM H19.00004 Data-driven predictions of root mean square pressure fluctuations from RANS simulations\textsuperscript{1} , GIACOMO LAMBERTI, CATHERINE GORLE, Stanford University — Wind engineering applications often employ computationally efficient Reynolds-averaged Navier-Stokes (RANS) simulations, even if the turbulence models can compromise the accuracy of the prediction. Furthermore, the estimation of turbulent quantities such as fluctuating pressure loads requires additional, potentially inaccurate, models. For example, empirical models to estimate the root mean square (rms) pressure fluctuations from of the mean pressure, turbulent kinetic energy and velocity, are known to produce incorrect results on the lateral facades of tall buildings. To address this problem, we propose a data-driven approach to determine the best functional form that relates high-fidelity data of rms pressure fluctuations to time-averaged variables predicted by RANS. The high-fidelity data is obtained from large-eddy simulations or wind tunnel experiments of a tall building at different wind directions. We perform RANS simulations for the same conditions and construct features from the resulting time-averaged quantities. Then, we employ machine learning to relate these features to the available training data. We investigate the ability of the data-driven model to provide predictions for wind directions or regions of the building that were not included in the training data.

\textsuperscript{1}This research is funded by NSF Grant Number 1635137.

8:52AM H19.00005 Area of Scalar Isosurfaces in Homogeneous Isotropic Turbulence\textsuperscript{2} , KEDAR PRASHANT SHETE, STEPHEN DE BRUYN KOPS, University of Massachusetts Amherst — A fundamental effect of fluid turbulence is turbulent mixing, which results in the stretching and wrinkling of scalar isosurfaces. Thus, the area of isosurfaces is of interest in understanding turbulence in general with specific applications in, e.g., combustion and the identification of turbulent/non-turbulent interfaces. We report measurements of isosurface areas in 28 direct numerical simulations (DNSs) of homogeneous isotropic turbulence with a mean scalar gradient resolved on up to 14256\textsuperscript{3} grid points with Taylor Reynolds number $Re$ ranging from 24 to 633 and Schmidt number $Sc$ ranging from 0.1 to 7. The continuous equation we evaluate converges exactly to the area in the limit of zero layer thickness. We demonstrate a method for numerically integrating this equation that, for a test case with an analytical solution, converges linearly towards the exact solution with decreasing layer width. By applying the technique to DNS data and testing for convergence with resolution of the simulations, we verify the resolution requirements for DNS that have been recently observed. We conclude that isosurface areas scale with the square root of the Taylor Péclet number $Pe$ between approximately 50 and 4429. No independent effect of either $Re$ or $Sc$ were observed.

\textsuperscript{2}Frontier Project FP-CFD-FY14-007

9:05AM H19.00006 A study of locking phenomenon of elliptical particle in shear flow with DNS . ZHIZHONG DING, Louisiana State University; Shell Company, CHENGUANG ZHANG, MIT, SHASHANK TIWARI, Louisiana State University, JYESHTHARAJ JOSHI\textsuperscript{1}, Institute of Chemical Technology, Mumbai, KRISHNASWAMY NANDAKUMAR, Louisiana State University, INSTITUTE OF CHEMICAL TECHNOLOGY, MUMBAI COLLABORATION, LOUISIANA STATE UNIVERSITY COLLABORATION — The understanding of the dynamics of arbitrary shaped particle(s) under shear flow is of great importance in design and scale-up Chemical Engineering equipment. In this study, we have carried out a series of numerical experiments on an elliptical cylinder particle, subjected to a 2D shear flow for moderate shear-based Reynolds number. The simulations have been performed using an in-house code Signed Distance Field - Immersed Boundary Method (SDFIBM) (Zhang et al., 2018). The degrees of freedom of the particle is limited and thus allows the particle to rotate only about a fixed position in space. Any translational and vertical movements are strictly limited to phase out the noises. This work demonstrates that there are two stages for elliptical cylinder particle in shear flow: the periodical rotating stage and stationary stage, divided by a critical Reynolds number. We further extend our investigation to include the effects of changing particle aspect ratio, flow confinement size and distance of particle from the wall. Frequency domain analysis have been carried out on the data to develop a better understanding of the locking phenomenon. The effect of a second ellipse in the vicinity of primary particle and its impact on the locking phenomenon has also been included.

9:18AM H19.00007 Direct Numerical Simulation in the Sub-critical and Supercritical regimes for Flow past a Stationary Sphere , SHASHANK S TIWARI\textsuperscript{1}, Institute of Chemical Technology, Mumbai, SHIVKUMAR BALE, University of Pittsburgh at Johnstown, ZHIZHONG DING, Louisiana State University; Shell Company, ASHWIN W. PATWARDHAN, Institute of Chemical Technology, Mumbai, KRISHNASWAMY NANDAKUMAR, Louisiana State University, JYESHTHARAJ B. JOSHI\textsuperscript{2}, Institute of Chemical Technology, Mumbai — The physical understanding of separating flows which exhibit critical phenomena under various flow conditions, have helped in designing various drag-reduction devices, turbulence generators, controllers, etc. Direct Numerical Simulation (DNS) of such separating flows helps to identify the flow structures and decipher the corresponding effects they have on the resulting forces. DNS being computationally intensive, the investigations for flow past a sphere has been limited to $Re \approx 10,000$. In this study, we test the capability of OpenFOAM in performing fully resolved DNS for $1000 < Re < 10^5$ Appropriate time and length scales have been used to adequately resolve the boundary layer. Extensive simulations were performed to test, optimize and set a benchmarking case for the domain size, mesh size, time-step and discretization schemes required for performing such computationally intensive simulations on a scalable parallel platform. Simulations were run till a statistically converged solution was obtained. The drag coefficients and pressure coefficients from the simulations were compared against experimental results available in literature and were found to be in good agreement.

9:31AM H19.00008 Large-Eddy Simulation of Propeller Crackback Using an Unstructured Overset Grid Method\textsuperscript{3} , THOMAS KROLL, WYATT HÖRNE, KRISHNAN MAHESH, University of Minnesota — We discuss the application of a novel unstructured overset grid methodology to compute the flow around a marine propeller. We consider the crackback mode of operation where the propeller rotates in the reverse direction while the vessel moves in the forward direction yielding highly unsteady loads. The numerical algorithm is that developed by Horne and Mahesh [J. Comput. Phys. (2019) 376:585-596] and addresses two significant challenges posed by the overset methodology - discrete conservation and scaling. The simulations consider open and ducted propellers. The results are compared to available experimental data and previous LES studies. Details of the flow field are discussed.

\textsuperscript{3}This work is supported by the Office of Naval Research (ONR).
In particular, we study the error in the transition location and the mean skin-friction due to the different coarse ($h$) and medium ($p$) meshes. The flow problem is simulated using a cylindrical grid composed of about 1.7 billion nodes. Earlier computations of the isolated propeller (open-water condition) demonstrated the accuracy of the overall methodology, via comparisons with both dynamometric measurements and Particle Imaging Velocimetry (PIV) visualizations. Three incidence conditions of the rudder are considered, corresponding to $0^\circ$, $10^\circ$ and $20^\circ$. Comparisons with the results in open-water conditions demonstrate that in the near wake the topology of the typical coherent structures shed by submarine propellers (tip and hub vortices) is not modified by the presence of the upstream hydrofoil at small incidence angles. In contrast, levels of turbulence within the wake are dramatically increased in the last configuration, featuring the rudder at $20^\circ$ of incidence. This substantial change is triggered by the separation occurring on the suction side of the hydrofoil, leading to a significant perturbation of the inflow conditions of the propeller.

We would like to acknowledge the support from the AFOSR under grant FA9550-16-1-0128, and US Army Research Office under grant W911NF-15-1-0505

10:10AM H19.00011 On the effect of wake passing on a low pressure turbine cascade using spectral/hp element methods, ANDEA CASSINELLI, Imperial College London, PAOLO ADAMI, Rolls-Royce plc., FRANCESCO MONTOMOLI, SPENCER J SHERWIN, Imperial College London — The developing and future interaction of HPC, high fidelity CFD and high order unstructured grid algorithms has the potential to allow for simulation-based research, analysis and design capability. Previous work focused on developing guidelines to leverage the use of high order spectral/hp element methods as a virtual cascade for turbomachinery applications. Building on the knowledge previously reported, we analyze a representative industrial low pressure turbine cascade subject to wake passing interactions at moderate Reynolds number, adopting the incompressible Navier-Stokes solver implemented in the Nektar++ software framework. The rotor-stator interaction is modelled by imposing appropriate Dirichlet boundary conditions. The impact of flow coefficient and reduced frequency is studied in conjunction with the Reynolds sensitivity. The analysis focuses in detail on the dynamics of the separation bubble on the suction surface looking at mean flow properties and turbulence kinetic energy budgets, comparing the main findings with experimental data.

We would also like to thank Rolls-Royce plc. for support and permission to publish this work.

10:23AM H19.00012 Numerical investigation of the flow in gas turbine blade trailing edge internal cooling passages, JAEHYUN RYU, WONTAE HWANG, Seoul National University — Gas turbine blades operate at very high temperatures, often beyond material limits. Internal and external cooling enable the blade to survive these extreme temperatures. The trailing edge of the blade is designed to be sharp for high aerodynamic efficiency, but this makes internal convective cooling poor at the corner. The effect of ribs was assessed in a right triangle channel containing a sharp corner, representing a simplified trailing edge. First, 45 angled ribs on the pressure and suction side walls were investigated. The Reynolds-averaged Navier-Stokes (RANS) results show fairly good agreement with previous results from magnetic resonance velocimetry (MRV) and large eddy simulation (LES). Different turbulence models were assessed, and the baseline explicit algebraic Reynolds stress model (BSL EARSM) was adequate in capturing the flow structure. Next, we optimized rib geometry via design of experiments (DOE), by changing the rib height to channel height ratio and rib angle. 3-level full factorial design (FFD) was used to determine the DOE points. Streamwise flow velocity at the sharp corner and friction factor were set as objective functions. The corner flow velocity increases as the rib is angled less toward the flow, at the penalty of an increase in friction factor.

Monday, November 25, 2019 8:00AM - 10:10AM – Session H20 Geophysical Fluid Dynamics Cryosphere 602 Claudia Cenedese, Woods Hole Oceanographic Institution

8:00AM H20.00001 Modeling the formation of wind-driven coastal polynyas, LAILAI ZHU, Princeton University, BHARGAV RALLABANDI, University of California, Riverside, MICHAEL WINTON, NOAA/Geophysical Fluid Dynamics Laboratory, HOWARD STONE, Princeton University — Polynyas are persistent, recurrent regions of open sea water surrounded by sea ice and/or land in the polar zones. We conduct a combined theoretical and numerical study on the dynamics and thermodynamics of the formation of a wind-driven latent-heat polynya near a coastline with and without curvature. In the limit of weak ice internal pressure, we propose a one-dimensional, continuous, mass- and momentum-conserving theory characterizing the offshore distribution of the ice velocity and the spatial-temporal evolution of the ice concentration. Using an open-source solver based on finite-element method, we simulate this process considering the rheological properties of the ice. The theoretical and numerical results agree well with each other in most cases, and the obtained steady-state polynya width qualitatively matches the corresponding climate data.
JUMPING FROST

8:26AM H20.00003 Lubricated gravity currents of power–law fluids1, AYALA GYLLENBERG, ROIY SAYAG, Ben Gurion University — The discharge of ice from power–law fluids into the ocean has the potential to induce climate change and a catastrophic rise in sea level. Significant ice discharge can occur via ice streams, bands of fast–moving ice lubricated by a mixture of water and clay. We present a fluid–dynamical model for such lubricated gravity currents that describes the axisymmetric spreading of a viscous, non–Newtonian fluid, such as ice, under thinning and melting. Both fluids are discharged at the origin at a time–dependent flux of a general power–law form. We investigate the model solutions by combined analytical and numerical methods. We find that the model admits self–similar solutions only in specific cases, such as when the top fluid is Newtonian or when the fluids are discharged at a certain time–dependent flux. When the flux is constant, similarity solutions are present when the viscosity of one fluid is much greater than that of the other fluid, as in the case of an ice sheet lubricated by water. In that case we find that the front of the lubricating fluid outstrips that of the power–law fluid, a phenomenon that has been observed in laboratory experiments.

1German-Israeli Foundation 1-2404-301.8/2015

8:39AM H20.00004 Lubricated gravity currents of strain–rate softening fluids, and the formation of ice-streams1, ROIY SAYAG, Ben Gurion University, PRAMODA KUMAR, Ashuka University, SHAHAR ZURI, Technion — Ice–sheet instabilities are believed to be closely associated with the flow of ice streams, bands of fast–flowing ice that carry most of the mass flux towards the edge of the ice sheet, where it ultimately melts or calves. The formation and evolution of ice streams is believed to be controlled by a complex hydrological network under the ice that sets the dynamic boundary conditions on the base of the ice. Fluid mechanically, such a system can be modelled as a viscous gravity current of strain–rate softening fluid lubricated by a relatively inviscid and denser Newtonian fluid. We present an experimental study of such flows that were discharged axially and radially at a constant rate. We investigate the evolution of the fronts of the viscous and the lubricating fluids, and how and why they form depend on the manifold dimensionless groups of the flow. We find two distinguished classes of patterns. In the first class, both fronts remain axisymmetric throughout the flow. In the second class, the initially axisymmetric front of the lubricating fluid evolves into a set of localised fingers, which drive the initially axisymmetric flow of the viscous fluid to develop patterns that are reminiscent to ice streams.

1German-Israeli Foundation 1-2404-301.8/2015

8:52AM H20.00005 Ice-Shelf Rippling From Temporally Varying Melt and Ice Flow, ANDREW WELLS, CHRIS MACMACKIN, University of Oxford — The Antarctic and Greenland ice sheets often discharge into the ocean through floating ice shelves. Ice-shelf geometry is controlled by the coupling of a viscous ice flow with basal melt driven by buoyant meltwater plumes rising through the warm and salty ocean along the sloping ice-shelf base. Motivated by recent observations of the spatial patterns of ice-shelf thickness, we assess the response of an ice shelf to a range of temporally-periodic forcing conditions. We model the depth-integrated viscous extensional flow of an ice shelf downstream of the grounding line, where the grounded ice transitions to the floating shelf. Melting is determined from a meltwater plume model with imposed subglacial discharge. We use a linear perturbation analysis to explore the sensitivity of the ice shelf geometry to periodic variation of the freshwater source flux for the meltwater plume, ice flux across the grounding line, and coupled variation of ice flux and grounding line position. Such periodic variation leads to propagating ripple-like features on the ice shelf base, with greatest sensitivity to varying ice influx with coincident grounding line motion. We analyse the mechanisms controlling ripple amplitude, and discuss potential implications for formation of ice-shelf basal terraces.

9:05AM H20.00006 Relaxation of ice-sheet uplift on a porous bed, CHING-YAO LAI, Columbia University, DANIELLE L. CHASE, Princeton University, LAURA A. STEVENS, TIMOTHY T. CREYTS, Columbia University, HOWARD A. STONE, Princeton University — When surface meltwater reaches the base of an ice-sheet with high flow rate, it peels apart the interface between the ice and bed, forming a water-filled blister and inducing ice-sheet uplift. The uplift relaxes after water injection, with a wide range of relaxation times (Geodetic observations show relaxation occurs over hours to days). Improved characterization of water flow at the base of ice sheets is vital for predicting ice-sheet dynamics and mass loss when the bed is lubricated. Although properties of the lubricated porous sheet beneath the ice impact ice sliding, the permeability of the porous sheet has not been measured directly and remains unknown. Here, we show that the elastic relaxation of a water-filled blister above a porous substrate can be used to probe permeability. Combining field data, a mathematical model, and laboratory experiments, we show that the blister height decreases exponentially with time as the water in the blister permeates through the porous sheet. We find that the relaxation dynamics obeys a universal law with a time scale involving the thickness and permeability of the porous sheet, water viscosity, and the Young’s modulus of ice. We show that the range of observed relaxation times can be explained by the evolving permeability of the porous sheet. Our reduced-order model better characterizes the evolution of bed permeability based on surface observations.

9:18AM H20.00007 Direct numerical simulations of ice melting in a turbulent ocean1, LOUIS-ALEXANDRE COUSTON, British Antarctic Survey — In this talk I will present preliminary results of direct numerical simulations of ice melting in a stratified turbulent ocean. The model solves the evolution of the turbulent fluid phase and of the diffusive solid ice phase, due to melting and freezing, in a fully coupled way. This is done by combining a highly-efficient fully-spectral Direct Numerical Simulation (DNS) code with a novel formulation of the equations for the solid and liquid phases of water based on the phase-field method, which is routinely used in metallurgy. DNS enables turbulent motions to be simulated without approximation, i.e. solving Navier Stokes equations, while the phase-field method allows the ice-ocean interface to be rough and evolve in response to melting. I will present results on the turbulent boundary layer and on the self-generated roughness at the ice-ocean interface for fresh water. The ultimate goal of this work is to propose a new DNS-based parameterization of the melting process at rough ice-ocean boundaries that takes into account the effects of temperature and salt stratification, and flow velocities.

1The project leading to this application has received funding from the European Unions Horizon 2020 research and innovation programme under the Marie Sklodowska-Curie grant agreement No 793450
9:31AM H20.00008 Glacial Squeegee: Elastic Landau-Levich and the Tidal Modulation of Ice Streams, KATARZYNA WARBURTON, DUNCAN HEWITT, JEROME NEUFELD, University of Cambridge — Glacier speed is sensitive to fluctuations in subglacial water pressure. For marine ice sheets, the tidal cycle is linked to the upstream pressure fluctuations as water enters and exits the subglacial environment across the grounding line. We analyse the elastic analogue of the Landau-Levich dip-coating problem, in which a plate (here the earth) is withdrawn from a bath of fluid (the ocean) on whose surface lies a thin elastic sheet (the ice), for arbitrary angle of withdrawal \( \delta \) (basal slope). The flow is controlled by the elasticity number, \( E_l \), which is a measure of the relative importance of viscous and bending stresses, and \( \delta \). The leading order solution for small \( E_l \) is a steady profile in which the thickness of the film deposited on the plate is found. The breakdown of this asymptotic regime in the limit of large \( E_l \) is also discussed. These solutions are interpreted in the context of the tidal grounding line problem, and related to observations from the Rutford Ice Stream.

9:44AM H20.00009 Ice floe dispersion from moderate remote sensing imagery\(^1\), ROSALINDA LOPEZ, University of California Riverside, MONICA M. WILHELMS, Department of Mechanical Engineering, University of California Riverside, WILHELMS LAB TEAM — Sea ice transport directly affects the heat budget and freshwater flux in the Arctic. To understand the Arctic climate system, it is thus important to quantify the dispersion regime of free-drifting sea ice. In this study, we employed an in-house algorithm to automatically process Moderate Resolution Imaging Spectroradiometer satellite images and track ice floes (0 to 65 km) along the eastern coast of Greenland during the spring of 2017. By quantifying the drift fields, the dispersion regime of the ice floes was analyzed to understand the drivers of sea ice transport. Preliminary results show that, as expected, in the presence of a strong shear flow as the East Greenland Current, the absolute dispersion of ice floes grows quadratically in time. Further analysis of the fluctuating component of sea ice velocities also yields an absolute dispersion that grows quadratically in time at short time scales (few days). It was observed, however, that this behavior changes when considering longer time scales as the influence of the underlying eddy field becomes more prominent. We examine the effect of small scale oceanic turbulence on sea ice drift and discuss the feasibility of extending our study to improve our understanding of sea-ice ocean interactions.

9:57AM H20.00010 Enhanced submarine melting of glaciers due to the effect of sediments on subglacial discharge plumes\(^1\), CLAUDIA CENEDESE, Woods Hole Oceanographic Institution, CRAIG MCCONNOCHIE, University of Canterbury, JIM MCELWAINE, Durham University — Recent studies suggest that marine terminating glacier faces meet at particularly high rates where subglacial discharge plumes are present. These subglacial discharge plumes have high sediment concentrations, as revealed by the surface expression of some of them, yet the impact of suspended sediment on the plume dynamics and the melting has, until now, been overlooked. Recent laboratory experiments and Direct Numerical Simulations (DNS) suggest that the sediment load could have an important and complex effect on the plume dynamics and thus the melting of the ice face. In particular, dilute concentrations of small and dense particles can increase the entrainment of ambient waters into the plume as much as 50\%, leading to a 50\% increase in the melt rate. In these experiments and simulations, the settling velocity of the particles is smaller than and in the opposite direction to the plume load could have an important and complex effect on the plume dynamics and thus the melting of the ice face. In particular, dilute concentrations of small and dense particles can increase the entrainment of ambient waters into the plume as much as 50\%, leading to a 50\% increase in the melt rate. In these experiments and simulations, the settling velocity of the particles is smaller than and in the opposite direction to the plume velocity at all heights and particle inertial clustering, leading to convective instability in the fluid, is thought to be the mechanism responsible for the enhanced entrainment.

Monday, November 25, 2019 8:00AM - 10:36AM — Session H21 Drops: Impacts with Solids I

8:00AM H21.00001 Droplet Dynamics Post Oblique Surface Impact\(^1\), VANESSA KERN, CATHY JIN, PAUL STEEN, Cornell University — Oblique droplet impact onto dry surfaces is ubiquitous in industry and nature, yet scarce in the literature. Here we investigate the post-impact dynamics of capillary water droplets obliquely impacting homogeneous chemically-prepared hydrophilic and hydrophobic surfaces. We analyze high-speed images of the impact event. Pre-impact Weber numbers range from 0-16. Impinging angles range from 0-53\(^\circ\). We observe that the drop spreads to a greater extent and forms a thinner film on hydrophilic surfaces than on hydrophobic ones. Post-impact Weber numbers range from 0-16. We observe that the drop spreads to a greater extent and forms a thinner film on hydrophilic surfaces than on hydrophobic ones. Post-impact Weber numbers range from 0-16. We observe that the drop spreads to a greater extent and forms a thinner film on hydrophilic surfaces than on hydrophobic ones. Post-impact Weber numbers range from 0-16. We observe that the drop spreads to a greater extent and forms a thinner film on hydrophilic surfaces than on hydrophobic ones. Post-impact Weber numbers range from 0-16. We observe that the drop spreads to a greater extent and forms a thinner film on hydrophilic surfaces than on hydrophobic ones. Post-impact Weber numbers range from 0-16. We observe that the drop spreads to a greater extent and forms a thinner film on hydrophilic surfaces than on hydrophobic ones.

8:13AM H21.00002 Contact-line Fluctuations and the Dynamics of Wetting, JOEL DE CONINCK, University of Mons — Using MD simulations, we have shown previously that the fluctuations about the mean position of the contact line may be interpreted in terms of an overdamped one dimensional Langevin harmonic oscillator of stiffness \( k \) and demonstrated a relationship between the time scale of the fluctuations of the contact line, the time decay of the oscillations, and the contact-line friction. Here, we extend this work to study the fluctuations when the contact lines are moving, yielding dynamic advancing and receding contact angles that differ from their equilibrium values. A steady dynamic state is achieved by moving the plates in opposite directions at constant velocities. Under these conditions, we obtain an identical Langevin expression to that found at equilibrium, but now with the harmonic term centered about the mean contact line and a fluctuating capillary force arising from the fluctuations of the dynamic contact angle around its mean value. During the talk, we will show that the contact-line fluctuations are the same irrespective of whether the contact line is at equilibrium or moving and contain all the information necessary to predict the dynamics of wetting.

8:26AM H21.00003 Contact time of water drop on cylindrical superhydrophobic surfaces\(^1\), CHONGYEOP LEE, JEONGHOON HAN, Kyung Hee University, WONJUNG KIM, Sogang University, CHANGWOOW BAE, Kyung Hee University, DONG WOO LEE, SEUNGWON SHIN, Hongik University, YOUNGSUK NAM, Kyung Hee University — When the water drop is impinged upon a cylindrical superhydrophobic surface with varying diameter, its contact time with the surface decreases over that on the flat superhydrophobic surface. However, the prediction of the contact time remains challenging due to the complex drop spreading dynamics on cylindrical superhydrophobic surface after impact. Here, based on systematic experimental and numerical studies, we develop a scaling relationship for the contact time reduction on the cylindrical superhydrophobic surface. We show that non-dimensionalized contact time can be expressed as a function of a single dimensionless parameter, which is expressed as the combination of the Weber number and the ratio of the cylinder diameter to the drop diameter.

\(^1\)National Research Foundation of Korea - 2017R1A2B4008028, 2019R1A2C2004607, 2017R1D1A1B03028518
gas on splashing at high Weber and Reynolds numbers, project no. BA 4953/3. Gordillo [Phys. Rev. Lett. 113, 024507 (2014)], who proposed that these aerodynamic forces are the responsible for splashing.

The results show that, under our experimental conditions, liquids spread with a maximum advancing contact angle greater than 87 degrees, regardless of the liquid or substrate properties. Our results also show that existing dimensionless groups, i.e. the splashing parameter (K) and the capillary number (Ca), are not appropriate to characterise the splashing behaviour. Finally, we show that the splashing ratio β and the maximum dynamic advancing contact angle, appropriately divides the splashing and no-splashing behaviour.

1 Royal Society (Grants No. URFuRn180016 and No. RGFuEAn18002), the EPSRC (Grant No. EP/P024173/1), the Mexican Energy Ministry (SENER), CONACyT Mexico, and the Welsh Funding Office (WEO)

8:39AM H21.00004 Role of the Dynamic Contact Angle on Splashing1, MIGUEL A. QUIETZERI-SANTIAGO, Queen Mary University of London, KÉNSUKE YOKOI, Cardiff University, ALFONSO A. CASTREJN-PITA, University of Oxford, J. RAFAEL CASTREJN-PITA, Queen Mary University of London — A drop impacting onto a solid dry substrate can, among other several results, splash or spread over the solid surface. The result depends not only on the droplet properties and speed, but on a wide range of parameters. Although many studies have aimed at finding scaling arguments to characterise splashing, the exact combination of parameters and their influence have remained elusive. In this work we perform a systematic study of liquid droplets impacting onto various solid substrates ranging from completely wetting to superhydrophobic. The experimental approach uses high-speed imaging and image analysis to recover the contact angle as a function of the spreading velocity. We show that, under our experimental conditions, liquids spread with a maximum advancing contact angle greater than 87 degrees, regardless of the liquid or substrate properties. Our results also show that existing dimensionless groups, i.e. the splashing parameter (K) and the capillary number (Ca), are not appropriate to characterise the splashing behaviour. Finally, we show that the splashing ratio β and the maximum dynamic advancing contact angle, appropriately divides the splashing and no-splashing behaviour.

8:52AM H21.00005 Impact dynamics of ferrofluid drop on superhydrophobic surface under horizontal magnetic field1, NILAMANI SAHOO, DEVRAJAN SAMANTA, PURBARUN DHAR, Indian Institute of Technology Ropar — In this study, we focus on impact of ellipsoidal or columnar droplet by horizontal magnetic field on a non-wetting substrate and investigates experimentally the effect of Weber number (We) and magnetic Bond number (Bo_m). The orthogonal spreading depends on the magnitude of applied magnetic field (manifested through Bo_m), since the applied field alters the spherical shape of pre-impact drop into either ellipsoidal or columnar drop. The orthogonal spreading induces non- axisymmetric distribution pre-impact inertial energy along the transverse and longitudinal axes of the applied magnetic field, promoting rebound suppression for a fixed We. With increase in Bo_m, the nature of orthogonal spreading is more prominent to break symmetry retraction as observed experimentally. In addition, at higher orthogonal spreading ratio, the shattering of liquid lamella occurs due to nucleation of holes at different locations after post impact during retraction phase. We can suggest that the shattering of liquid lamella is critically dependent on the thickness of the liquid film after post impact and the wettability of the surface.

1 DS and PD would like to thank IIT Ropar for funding the present work (vide grants 9-246/2016/IITRPR/144 & IITRPR/Research/193 respectively)

9:05AM H21.00006 A theory on the spreading of droplets, JOSE GORDILLO, GUILLAUME RIBOUX, ENRIQUE S. QUINTERO, Universidad de Sevilla — Here we provide a self-consistent analytical solution describing the unsteady flow in the slender thin film which is expelled radially outwards when a drop hits a dry solid wall. Thanks to the fact that the fluxes of mass and momentum entering into the toroidal rim bordering the expanding liquid sheet are calculated analytically, we show here that our theoretical results closely follow the experimentally measured time-varying position of the rim with independence of the wetting properties of the substrate. The particularization of the equations describing the rim dynamics at the instant the drop reaches its maximal extension which, in analogy with the case of Savart sheets, is characterized by a value of the local Weber number equal to one, provides an algebraic equation for the maximum spreading radius also in excellent agreement with all the experimental data available in the literature. The self-consistent theory presented here provides us with the time evolution of the thickness and of the velocity of the rim bordering the expanding sheet. We also test these predictions and show that our theory is also able to predict the splash threshold velocity when the substrate is superhydrophobic and also the velocities and the diameters of the droplets ejected.

9:18AM H21.00007 Axisymmetric Lattice Boltzmann Simulation of Droplet Impact on Spherical Surfaces1, XIN YONG, HUSSIN DALGAMONI, Binghamton University — Droplet impact on solid surfaces plays important roles in many engineering applications, in which the ability to exert control over the detailed dynamics is critical. While past studies have established a complete understanding of droplet impact on flat substrates, what we know about the impact dynamics on curved surfaces is limited. This work simulated the normal impact of droplets on spherical surfaces with physical density and viscosity contrasts in the low Weber number regime, in which droplet deformation is assumed to be axisymmetric. We extended our recently developed axisymmetric free-energy lattice Boltzmann method (LBGM) to capture droplet wetting and contact line motion on a curved surface. The conventional staircase approximation of curved boundaries was used to reduce computational cost. Its accuracy was validated by the static wetting simulations. The impact simulations show that surface curvature and wettability significantly affected the spreading and recoiling of droplet. Five impact outcomes were observed, which ranges from deposition to total rebound. An impact phase diagram was constructed and correlated with the total contact time to provide guidelines for surface design for anti-icing applications.

9:31AM H21.00008 Experimental and numerical study of the effect of surrounding gas on splashing at high Weber and Reynolds numbers1, DAVID A. BURZYNSKI, STEPHAN E. BANSMER, Technische Universität Braunschweig — We investigated the influence of the surrounding gas on a droplet impacting a smooth dry glass surface at high Weber and Reynolds numbers. We analyzed experimentally the splashing outcome by measuring the size, velocity, and angle of the secondary droplets and by calculating the total volume ejected. Numerical simulations complement our study by providing detailed information about the flow in the liquid lamella and the surrounding gas. The results show that gas entrainment is not the mechanism responsible for splashing and demonstrate that splashing is influenced first by the density, second by the viscosity, and lastly by the mean free path of the surrounding gas. The simulations are used to estimate the forces acting on the ejected lamella and to compare it with the theory of Ribol & Gordillo [Phys. Rev. Lett. 113, 024507 (2014)], who proposed that these aerodynamic forces are the responsible for splashing.

9:44AM H21.00009 Surrounding gas-independent splash at high-velocity drop impact with a projected smooth solid surface\(^1\). MASAo WATANABE, TAKU ASHIDA, KAZUMICHI KOBAyASHI, HIROYUKI FUJII, Hokkaido University, TOSHIYUKI SANADA, Shizuoka University — We study a drop impact on a fast-moving smooth solid plate in a reduced-pressure condition. A water drop of radius \(R = 1.1\) mm was released from a rest needle in a stainless vacuum chamber; then, the free falling drop was brought into collision with a vertically upward flying solid impact plate which was projected by an iron bullet accelerated by a coilgun. The impact plate consisted of a cover glass with a static contact angle of 60° and a surface roughness \(R\) of 2.1 nm, adhered to an acryl plate. The surrounding gas pressure was varied between 1 and 100 kPa, and the impact velocity was varied between 4.2 and 33 m/s. The drop impact on a smooth solid plate with high impact velocity and the subsequent splash was recorded by a high-speed video camera at a frame rate of 1,000,000 fps at pixel resolution of 16.1 \(\mu\)m/pixel. In a reduced-pressure condition, preceding the occurrence of corona splash, fine daughter droplets, possibly smaller than those observed in corona splash, fly extremely fast along the solid surface only for a few microseconds. The experimental results show that this splashing is independent of both the surrounding gas pressure and gas species. We discuss the threshold of the occurrence of this splashing and identify the mechanism for this splashing.

9:57AM H21.00010 Air entrapment under drop impacts on soft solids\(^1\). KENNETH R. LANGLEY, KAUST, ALFONSO A. CASTREJON-PITA, University of Oxford, S. T. THORODDSEn, KAUST — Prior studies have found that soft solids delay the critical velocity at which drops begin to splash upon impact [1]. We investigate the effects of the surface compliance on the air cushioning at the bottom of a liquid drop impacting onto a soft solid and the resulting entrapment of a central bubble using high-speed interferometry at 5 million frames per second and spatial resolution of 1.05 \(\mu\)m/pixel. The soft solid delays the effects of gas compressibility. We also observe extended gliding of the drop as it initially avoids contact with the surface and spreads over a thin layer of air and investigate the threshold velocity for the onset of gliding. Such extended gliding layers have previously been seen for high viscosity drop impacts [2], but not for low viscosity drops. Additionally, we observe the dynamics as the drop spreads near the splashing threshold to observe effects of the compliance on the ejected lamellae. [1] Howland, C. J., Antkowiak, A., Castrejón-Pita, J. R., Howison, S. D., Oliver, J. M., Style, R. W., & Castrejón-Pita, A. A. (2016). Phys Rev Lett, 117 (18), 184502. [2] Langley, K., Li, E. Q., & Thoroddsen, S. T. (2017). J Fluid Mech, 813, 647-666.

10:10AM H21.00011 Characterizing the wettability/non-wettability transition during drop impact\(^1\). HARISH DIXIT, PRAVEEN SHARMA, Indian Institute of Technology Hyderabad — Recent experiments have shown a new bouncing mechanism on smooth surfaces where the drop is supported on a thin cushion of gas beneath it. Using incompressible high-resolution computations, we study drop impact dynamics at moderate speeds of impact. We restrict our attention to parameters where drop undergoes complete rebound and show that five distinct regimes can be identified in a Reynolds-Weber number phase diagram. In a broad sense, a stable gas cushion can be formed for low Reynolds number but for a wide range of Weber numbers. With increasing Reynolds/Stokes number, the gas film undergoes rupture either in an annular ring near the drop periphery or near the center of the drop. Each of the five regimes differs in the shape of the gas film near the impact surface. The exact transition boundary between wettability-independent and wettability-dependent bouncing is difficult to determine, but the simulations are found to be in good agreement with known scaling laws for initial deformation height, maximum spreading radius and minimum thickness of the gas film attained. Access to velocity and surface energy scaling laws is difficult to determine, but the simulations are found to be in good agreement with known scaling laws for initial deformation height, maximum spreading radius and minimum thickness of the gas film attained. Access to velocity and surface energy scaling laws is difficult to determine, but the simulations are found to be in good agreement with known scaling laws for initial deformation height, maximum spreading radius and minimum thickness of the gas film attained.

10:23AM H21.00012 Some additional considerations on the splashing of droplets. GUILLAUME RIBOUX, JOSE GORDILLO, Universidad de Sevilla — When a drop of a low viscosity liquid impacts against a smooth solid substrate at a velocity \(V\), a liquid sheet of thickness very small compared to the drop radius is expelled tangentially to the substrate at high velocity \(V^*\). If the impact velocity is such that \(V > V^*\) with \(V^*\) the critical velocity for splashing, the edge of the expanding liquid sheet lifts off from the wall as a consequence of the gas lubrication force at the wedge region created between the advancing liquid front and the substrate. In the present talk, we show that the magnitude of the gas lubrication force is limited by the values of the slip lengths at the gas-liquid interface and at the solid. We demonstrate that the splashing regime changes depending on the value of the ratio of the slip lengths, a fact explaining the spreading-splashing-spreading-splashing transition for a reduced value of the surrounding gas pressure as the drop impact velocity increases. We also provide an expression for \(V^*\) as a function of the inclination angle of the substrate, the drop radius, the material properties of the liquid and the gas and the mean free path of gas molecules.

---

Monday, November 25, 2019 8:00AM - 10:36AM – Session H22 Drops: Heat Transfer and Evaporation I

8:00AM H22.00001 On the effect of wicking on droplet cooling\(^1\). MANUEL AULIANO, DAMIANO AULIANO, MARIA FERNANDINO, NTNU, PIETRO ASINARI, Politecnico di Torino, CARLOS DORAO, NTNU — Enhancing the droplet cooling is important for an efficient and safe design of thermal management applications, such as electronics, nuclear and aeronautics industry. For enhancing the droplet cooling heat transfer, it is desirable that the droplet spreads as much and as fast as possible. In this regard, tailoring the surface with micro/nanostructures is a promising approach that controls the surface wettability and the heat transfer performance. This work focuses on the effect of the wicking of super-hydrophilic stochastic Si nanowires on droplet evaporation from low to high temperatures. The research method consisted in fabricating Si nanowires with different heights and characterizing the wickability of the surfaces prior to the heat transfer experiments. The evaporation performance of the processed samples has been discussed in terms of the droplet evaporation time. A significant reduction of the evaporation time and shift of the Leidenfrost point were observed and attributed to the strong wicking provided by the nanostructured surfaces.

A Switchable Wettability Surface for Condensation Heat Transfer Manipulation

Jonathan Ludwicki, Paul Steen, Cornell University — The development of variable heat transfer devices is critical to enabling human exploration missions beyond low-Earth orbit (2015 NASA Technology Roadmaps). Here, we show the ability to manipulate condensation heat transfer performance via a surface with temperature-dependent wettability. Specifically, a nanostructured poly(N-isopropylacrylamide) surface was developed to switch the surface wettability between hydrophobicity and hydrophilicity via temperature stimulus. The hydrophobic surface condensation formation produces flooded dropwise condensation, which shows a two-times larger heat transfer coefficient versus filmwise condensation in the hydrophilic state. Such surfaces hold promise as a means to control heat transfer during flow condensation in spacecraft two-phase flow thermal control systems.

Freezing a rivulet

Antoine Monier, Sorbonne Université, CNRS, UMR 7190, Institut Jean Le Rond d’Alembert; F-75005 Paris, France; Axl Huerre, Christophe Josserand, Laboratoire d’Hydrodynamique (LadHyX), UMR 7646 CNRS-Ecole Polytechnique, IP Paris, 91128 Palaiseau CEDEX, France; Thomas Don, Sorbonne Université, CNRS, UMR 7190, Institut Jean Le Rond d’Alembert; F-75005 Paris, France; Laboratoire d’Hydrodynamique (LadHyX), UMR 7646 CNRS-Ecole Polytechnique, IP Paris; 91128 Palaiseau, TEAM, Sorbonne Université, CNRS, UMR 7190, Institut Jean Le Rond d’Alembert; F-75005 Paris; France; Team — We study experimentally the solidification of a water rivulet flowing down an inclined plane cooled to subzero temperatures. The growth of the ice is described by two successive regimes with different dynamics. First, the ice grows as if the water was not flowing, well described by a classical 1D Stefan problem. Then, thermal convection from the constant water supply starts to play a role in the solidification process. Finally, the system reaches a stationary state where water flows on a peculiar ice structure. The surprising linear geometry of this structure, with distance from the water injection point, is explained through scaling arguments. The physical explanation relies on the growth of the water boundary layer with respect to the finite size of the water rivulet. When the thickness of the thermal boundary layer reaches the free surface, the surface temperature of the water decreases with the plane position, allowing us to recover the linear behavior of the ice structure.

8:39AM H22.00004 Ice patterns formation in freezing drop impacts

Thomas Seon, Institut d’Alembert, CNRS - Sorbonne Université, Virgile Thievenaz, Institut d’Alembert, Sorbonne Université, Christophe Josserand, LadHyX, CNRS - Ecole Polytechnique — We investigate the different shapes taken by a water drop frozen during its impact on a cold surface. The capillary hydrodynamics of a water film dewetting on ice, coupled with its vertical solidification, is quantitatively characterized. This allows us to understand and predict the formation of the emerging patterns. Finally, we show that this experiment enables a measurement of the contact angle of water on ice, whose value is still debated.

Frost pattern on surfaces with millimetric serrated features

Kyoo-Chul Park, Yuehan Yao, Tom Zhao, Emma Feldman, Christian Machado, Neelesh Pantankar, Northwestern University — Numerous studies have focused on a low surface energy coating and a micro/nanoscale surface texture to design functional surfaces that delay frost formation and reduce ice adhesion. However, the scientific challenges for long-term icophobic surfaces have not been fully addressed because of the complexity of mechanical freezing. Inspired by the suppressed frost formation on concave regions of natural leaves, here we report findings on the frosting process on surfaces with various serrated structures. Dropwise condensation, the first stage of frosting, is enhanced on the peaks and suppressed in the valleys when the wavy surface is exposed to humid air, causing frosting to initiate from the peak. The condensed droplets in the valley are then evaporated, resulting in a non-frost band. The effects of surface topography on the frost patterns are systematically studied by varying the serrated geometry defined as the vertex angle, and numerically modeling the spatial distribution of diffusion flux of water vapor on the wavy surface. Under different ambient humidity levels, the magnitudes of diffusion flux at the non-frost boundaries of the surfaces are nearly identical, implying that the critical value of diffusion flux is the key to understanding the non-frost pattern.

9:05AM H22.00006 Final fate of a Leidenfrost droplet: Explosion or takeoff

Sijia Lyu, Tsinghua University, Vargheese Mathai, Brown University, Yujie Wang, Tsinghua University, Benjamin Sobac, Pierre Colinet, University of Twente, Deletre Lohse, University of Twente, Chao Sun, Tsinghua University, Center for Combustion Energy, Department of Energy and Power Engineering, Team, Engineering Research Center Collaboration, Tips-Fluid Physics Collaboration, Physics of Fluids & Max Plank Center Collaboration — When a liquid droplet is placed on a very hot solid, it levitates on its own vapor layer, a phenomenon called the Leidenfrost effect. Although the mechanisms governing the droplet’s levitation have been explored, much is known about the fate of the Leidenfrost droplet. Here we report on the final stages of evaporation of Leidenfrost droplets. While initially small droplets tend to take off, unexpectedly, the initially large ones explode with a crack sound. We interpret these in the context of unavoidable droplet contaminants, which accumulate at the droplet-air interface, resulting in reduced evaporation rate, and contact with the substrate. We validate this hypothesis by introducing controlled amounts of microparticles and reveal a universal 1/3-scaling law for the dimensionless explosion radius versus contaminant fraction. Our findings open up new opportunities for controlling the duration and rate of Leidenfrost heat transfer and propulsion by tuning the droplet’s size and contamination.

Pattern formation from dried drops can be used to identify adulterated medicines

Yojana Carreon, Instituto de Investigaciones en Materiales, Universidad Nacional Autónoma de México; Ivan Cipriano-Urbano, Universidad Autónoma de Coahuila; Francisco Solorio-Ordaz, Jorge Gonzalez-Gutierrez, Facultad de Ingeniería, Universidad Nacional Autónoma de México, Roberto Zenit, Instituto de Investigaciones en Materiales, Universidad Nacional Autónoma de México — It is estimated that in Europe, from 2009 to 2012, 12.8 million of patients were exposed to counterfeit medicines. In Mexico, it is suspected that, between 2006 and 2013, many children suffering from cancer received distilled water instead of chemotherapeutic drugs. Fluid mechanics can be used to prevent such vile acts. Here we propose a simple method to detect the authenticity of medical substances, considering the patterns formed by dried droplets. The method is based on the structural analysis of patterns generated after the solvent of a drop of liquid medicine has evaporated over a solid substrate. We exploit the capillary flux and the ionic interactions as a natural aggregation mechanism to form patterns, which reveals unique structures for each active ingredient or drug. We demonstrate that the first-order statistics (FOS) and gray level co-occurrence matrix (GLCM) are sufficient metrics to distinguish among deposits generated by pure and adulterated drugs with an accuracy greater than 90%.

9:31 AM H22.00008 Crystal Critters: Growth and ejection of crystals from heated, superhydrophobic surfaces, SAMANTHA MCBRIDE, HENRI LOUIS GIRARD, KRIPA VARANASI, Massachusetts Institute of Technology. Evaporating a drop of a volatile liquid containing a non-volatile solute leads to crystallization of said solute due to rising concentrations exceeding the solubility limit. When a drop of salty water is evaporated on a hydrophobic surface, “salt globes” that mirror the shape of the drop form due to nucleation at the air/water interface. Here, we present an unusual phenomenon in which salt globes grow from an evaporating drop on a heated superhydrophobic surface proceed to self-eject from that surface via growth of crystalline tubules. We show that this phenomenon is due to a specific superhydrophobic texture that combines minimal contact points and an assortment of channels that allow vapor to escape. A large temperature gradient across the height of the drop concentrates vaporization near the substrate, and escaping vapor at contact points between substrate and liquid leads to growth of crystalline tubules. These tubules grow into “legs” causing the entire salt globe — and any remaining water — to lift off from the surface. We call these structures composed of salt globes balanced on tubule legs “crystal critters” due to their resemblance to biological forms. Following complete evaporation, the crystal critters have minimal contact with the substrate and can be easily removed; and could find application for anti-fouling surfaces for spray heat exchangers.

9:44 AM H22.00009 Drop impact on a coated inclined surface, SUHAS RAO TAMVADA, VARUN KULKARNI, NIKHIL SUBHASH SHIRODA, GAURAV KULKARNI, SUSHANT ANAND, University of Illinois at Chicago. The impact of a drop onto a surface is useful in assessing the water repelling attributes of substrates with a given wettability. Most studies have focused on drop impact on horizontal flat surfaces however oblique impact of a droplet onto a surface, representing more accurate scenarios such as impact onto turbine blades leading to ice accretion and pesticide spraying has not been investigated. To this end we study the gentle deposition of a droplet at different temperatures on paraffin wax coated on an inclined copper surface. We measure the distance and average velocity of droplet until it comes to a halt to evaluate the role of the impact conditions and surface inclination on the observed sliding behavior. As we increase droplet temperature enhanced melting of the wax layer promotes sliding of the droplet to larger distances eventually being arrested by the viscous drag due to the underlying melted wax layer. Of significant interest is the deviation from the typical stick-slip motion reported on inclined hydrophobic surfaces. Our studies evaluate the efficacy of wax coatings in promoting self-cleaning on inclined surfaces and their possible use in applications which demand expedient shedding of droplets.

9:57 AM H22.00010 Stability of evaporating sessile drops comprising binary mixtures, ADAM WILLIAMS, School of Engineering, The University of Edinburgh, GEORGE KARAPETAS, Department of Chemical Engineering, Aristotle University of Thessaloniki, PEDRO TENG, Jan de Viron, University of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, The University of Edinburgh. Spreading and evaporation of a binary mixture sessile drop is a highly dynamic and complex process governed by the interplay between capillary stress, evaporation, hydrodynamic flow, mass diffusion and surface tension, with both thermal and solutal Marangoni stresses also present. We examine the behaviour and stability of volatile wetting ethanol-water drops deposited onto heated substrates using both experiments and modelling. We take a one-sided approach, utilising lubrication theory to obtain a base state before assessing stability by performing a linear stability analysis evoking the quasi-steady-state approximation. Evolution equations are derived for the interface height, temperature and concentration fields, assuming that the mixture comprises two ideally mixed volatile components with a surface tension linearly dependent on both temperature and concentration. Numerically, the contact line is avoided by releasing the drop over a precursor film. Results from both simulations and experiments indicate that concentration gradients in binary drops give rise to super-spread, and, at high ethanol concentrations, contact line instability. Our initial stability analysis also confirms that the process is highly unstable.

10:10 AM H22.00011 Dynamics of evaporating and non-evaporating drops falling in air, JORGE CHAVARRIA, UNAM, Mexico, SAUL PIEDRA, Conacyt Cidesi-Centa, Mexico, JUAN ARBENEGUI-TROYA, Oxford, UK, LILIA MARGARITA HERNANDEZ, ISTEM, Mexico, GUILLERMO HERNANDEZ-CRUZ, UNAM, Mexico, A ALFONSO CASTREJON-PITA, Oxford, UK, EDUARDO RAMOS, UNAM, Mexico. We report experimental observations of the dynamics of evaporating and non-evaporating drops falling in air under the influence of gravity. We use water and acetone drops of approximately 1 mm initial diameter. The experimental rig allows us to observe and acquire the motion for more than 2 m which corresponds to almost one second of flight-time and 80% of its terminal velocity. Under these conditions, evaporation reduces the initial volume by approximately 50% when acetone is used. We find that the motion is rectilinear up to the point where the Reynolds number is 190 and 220 for evaporating and non-evaporating drops respectively. We suggest that under this regime the motion becomes helicoidal in both cases. It is observed that this Reynolds number coincides with the formation of hairpin vortices in the wake. The geometrical properties of the wake of the evaporating drops are visualized using a Schlieren technique. We developed a simple model to predict the position as a function time of evaporating and non-evaporating falling drops in rectilinear motion regime.

10:23 AM H22.00012 Drying water droplets: Suppression of the coffee-stain effect by letting them dry on a thin oil film, YAXING LI, Physics of Fluids group, University of Twente, CHRISTIAN DIDDENS, TIM SECHERS, Physics of Fluids group, University of Twente; Eindhoven University of Technology, HERMAN WIJSHOFF, Oce Technologies, B. V.; Eindhoven University of Technology, MICHEL VERSLUIJS, Physics of Fluids group, University of Twente, DETLEF LOHSE, Physics of Fluids group, University of Twente; Max Planck Institute for Dynamics and Self-Organization. We systematically study the evaporation of a water microdroplet put on a thin oil film, both experimentally and theoretically. First, the absence of an intercalated film between droplets and substrates is demonstrated by interferometry. The interfacial energies between the droplet, the oil film and the solid surface are the key parameters to determine the wetting characteristics. During evaporation, we measure the flow field with pIV, which shows that it is controlled by the contact line behavior and the wetting state of the film with the droplet. Once the microdroplet contains particles, they accumulate during the evaporation process. We experimentally finds that the final deposition of the particles is determined by the flow and by the movement of the contact line. We derive an analytical expression for the radial velocity profile in the flow field near the substrate, which proves that the hindering of evaporation at the rim of the droplet by the non-volatile oil meniscus prevents the flow towards the edge, and therefore suppresses the “coffee-stain effect.” We finally demonstrate that the final particle deposition can be manipulated by tuning the surface energy of the droplet by adding a specific amount of a surfactant.
8:00AM H23.00001 Turbulent superstructures in a zero pressure gradient turbulent boundary layer for the Mach number range $0.3 - 3.0^1$. MATTHEW BROSS, SVEN SCHARNOWSKI, CHRISTIAN J. KÄHLER, Bundeswehr University Munich — Meandering high- and low-momentum flow motions often called superstructures in turbulent boundary layers (TBLs) can extend up to several boundary layer thicknesses and contain a large portion of the layer’s turbulent kinetic energy. However, compared to the extensive number of incompressible investigations much less is known about the structural characteristics for compressible TBLs. Therefore, in this investigation TBLs on a flat plate over a range of Reynolds numbers and Mach numbers are considered in order to investigate the effect of compressibility on superstructures. Measurements are performed in the Trisonic Wind Tunnel Munich (TWM) for $0.3 < Ma < 3.0$ and a friction Reynolds number of $2700 < Re_f < 14600$ or $19800 < Re_{ij} = \rho u_i u_j \theta^2 / \mu_w < 40800$. Velocity fields are recorded using planar particle image velocimetry methods (PIV and stereo-PIV) in three perpendicular planes. Using multi-point statistical and spectrogram methods it was found that the streamwise variable lines associated with superstructures in the log-law layer slightly increase with Mach number and a distinct increase in the spanwise spacing of these structures was found for the supersonic cases when compared to the subsonic and transonic cases

8:13AM H23.00002 Optimal interpretation of measurements for enhanced-fidelity prediction of hypersonic boundary layer transition$^1$. DAVID BUCHTA, TAMER ZAKI, Johns Hopkins University — High-speed boundary-layer transition is extremely sensitive to the freestream disturbances which are often uncertain, thus compromising the accuracy of model predictions. To enhance the fidelity of simulations, we directly infuse them with measurements data. Our methodology is general and can be adopted with any simulation technique, e.g. parabolized stability equations or direct numerical simulations. An ensemble variational (EnVar) optimization is performed, whereby we determine the upstream flow that optimally reproduces the measurements. The cost function can account for our relative confidence in the model and the measurements, and judicious choice of the ensemble members improves convergence and reduces the prediction uncertainty. We demonstrate our data-augmented simulations for boundary-layer transition at Mach 4.5. Without prior knowledge of the freestream condition and using only wall measurements from an independent computation (true flow), all the relevant inflow disturbances are identified, and their amplitudes and phases are accurately predicted. We can then evaluate the entire flow field, beyond the original limited wall measurements. Our predicted flow compares favorably to the true unknown state, and discrepancies are analyzed in detail.

8:26AM H23.00003 Velocity-Vorticity Correlation Structure (VVCS) in Transitional Compressible Turbulent Boundary Layer$^1$. JUN CHEN, SHI-YAO LI, ZHEN-SU SHE, State Key Lab. for Turb. & Complex Sys., FAZLE HUSSAIN, Dept. Mech. Engrg., Texas Tech. Univ. — Velocity-vorticity correlation structure (VVCS) is used to measure the geometry of vortices in the numerically simulated compressible boundary layer (BL) at $Ma=2.25$, 4.5, and 6.0. Wall normal vorticity represented by $VVCS_{ij}$ corresponds to the low-speed streaks, flanked by counter-rotating streamwise vortices identified by $VVCS_{ij}$. The ratio of spanwise size to spanwise spacing of $VVCS_{ij}$ decreases from 3 to unity during transition to turbulence, indicating low-speed streaks gradually populating in $x$. During transition, correlation coefficient, $R_{ij}$ near the wall decreases at first then increases up to 0.55, indicating that the well-arranged hairpins break up into streamwise vortices, as observed in visualization of this region. At each $y$, the length of spanwise vortices identified by $VVCS_{ij}$ decreases fast during transition at all $Ma$, indicating thickening of BL, while becoming nearly invariant in $x$ in the well-developed region, consistent with a self-similar turbulent BL predicted by our theory (She2018JFM). For both $VVCS_{ij}$ and $VVCS_{ij}$ the spanwise size of vortices transverse size in the developed flow region. These results affirm the predominant role of the multi-layered structure and suggest new possibilities for control of turbulent flow.

8:39AM H23.00004 The post-singularity structure in the boundary-layer flow induced by a rotating sphere. JIM DENIER, SOPHIE CALABRETTO, Macquarie University — The flow induced by a rotating sphere has long held the interest of fluid mechanists. This simple flow provides a paradigm for the study of colliding boundary layers; in the case of the sphere the boundary-layer collision occurs when fluid is advected from the poles to the equator. The collision process is the physical manifestation of a finite-time singularity in the boundary-layer equations. Here we will present new experimental and computational results which demonstrate that the collision process results in a smooth separation of flow within the boundary layer at the equator and into a radial jet. Our results demonstrate that existing theories for the post-singularity structure do not provide an accurate description of the flow.

8:52AM H23.00005 The Leading Edge theory: a new insight into the laminar Boundary Layer. MOHAMMAD GABR$^2$, Independent Researcher — The flow properties at the leading edge of a flat plate represent a singularity to the Blasius laminar boundary layer equations; by applying the diffusion equation where the velocity of a moving flat plate in a stationary fluid is diffused to the far field, the leading edge velocity profiles are studied. Experimental observations as well as the theoretical analysis show an exact Gaussian distribution curve as the original starting profile of the laminar flow. To conclude; the main key results are as follows:

1The velocity profiles at the leading edge of a flat plate are Gaussian Curves that grow in space and time; whereas the Blasius velocity profile is a part of the general Gaussian curves solution.

2A new method to calculate the friction drag is successfully tested, based on the displacement area of the leading edge velocity profile.

3In order to obtain the final physical proof of the new theory it is recommended to carry out experiments using an ultra-thin flat plate moving in a stationary fluid and measuring the velocity profiles at the leading edge with different measurement techniques.

9:05AM H23.00006 Boundary-layer flow of air over a falling soap film$^1$. YUNA HATTORI, RORY CERBUS, JULIO BARROS JR., PINAKI CHAKRABORTY, Okinawa Institute of Science and Technology Graduate University — A falling soap film is a well-known experimental setup to realize two-dimensional flows in a laboratory. The soap film is invariably embedded in ambient air, which, in turn, is set to motion due to the falling film. We experimentally measure the velocity profile in the air using Particle Tracking Velocimetry (PTV). We find that the measured velocity profile conforms well to theoretical predictions using boundary-layer approximation. We discuss some implications of our results on the modeling of geophysical flows.

1Okinawa Institute of Science and Technology Graduate University
and biofilm like surfaces will be discussed and flow measurements will be presented.

velocimetry, and in situ measurement of the biofilm replacement with a line scanner. Comparisons of the resistance curves for the rigid replicas (i.e. non-evolving, such as faux fur), and their own three-dimensionally printed rigid replicas in a controlled environment. The surfaces will be exposed to flow raised additional questions. In this study, it is proposed to characterize biofilm like surfaces that have a more stable formation however, it is often attributed to the surface roughness, compliance, and the presence of undulating streamers in the flow boundary. Recent studies on living biofilms and rigid analogs have helped to address this very issue with acknowledgement that the biofilm evolution over time as it is exposed to flow raised additional questions. In this study, it is proposed to characterize biofilm like surfaces that have a more stable formation (i.e. non-evolving, such as faux fur), and their own three-dimensionally printed rigid replicas in a controlled environment. The surfaces will be evaluated in the Skin-Friction Flow Facility at the University of Michigan using streamwise pressure drop measurements, planar particle image velocimetry, and in situ measurement of the biofilm replacement with a line scanner. Comparisons of the resistance curves for the rigid replicas and biofilm like surfaces will be discussed and flow measurements will be presented.

9:31AM H23.00008 Augmenting Restricted Nonlinear Turbulence to Capture Scale Separation1, BENJAMIN MINNICK, DENNICE GAYME, Johns Hopkins University — The restricted nonlinear (RNL) dynamics comprises a streamwise constant mean flow interacting with a dynamically restricted perturbation field. This model aims to capture key features of wall-bounded turbulence with reduced computational expense. Constraining the nonlinear interactions leads to a reduced representation in which the RNL dynamics are supported by a small number of streamwise varying modes (non-zero streamwise Fourier coefficients) interacting with the streamwise mean, which captures statistical features of low Reynolds turbulence. To correctly capture momentum transfer at moderate Reynolds numbers where scale separation emerges, the streamwise varying modes must correspond to the small wave lengths associated with the outer-layer peak of the surrogate dissipation spectra. At higher Reynolds numbers where there is a clear separation of scales, we expect the model to require additional large scales consistent with triadic interactions of the small scales. Here, we simulate these interactions by including a large scale streamwise varying mode which is permitted to interact nonlinearly with small scale modes. We demonstrate that this augmented RNL (ARNL) model reproduces key flow statistics for Reynolds numbers as high as $Re_r \approx 5200$.

9:44AM H23.00009 Convolutional neural networks for identifying coherent turbulent structures, ERIC JAGODINSKI, SIDDHARTHA VERMA, Florida Atlantic University — Identifying coherent structures and extreme events is key to understanding the physics of near-wall turbulent flows. Deep convolutional neural networks were originally developed for image recognition, but have immense potential for extracting features in multi-dimensional vector fields. Here, velocity fields extracted from Direct Numerical Simulations (DNS) of a periodic turbulent channel flow were input into a convolutional neural network in order to identify coherent structures and extreme events. The domain was reduced to a Minimal Flow Unit (MFU), as done in Jimenez (1991), and features were labeled for training the neural network using thresholding. Once trained, the network is able to correctly classify coherent structures and extreme events in the flow field.

9:57AM H23.00010 Dynamics and structure of backflow events in turbulent channels1, JOSE CARDESA-DUENAS, Univ Politecnica de Madrid, JASON MONTY, University of Melbourne, JULIO SORIA, Monash University, MIN CHONG, University of Melbourne — A statistical description of flow regions with negative streamwise velocity is provided based on simulations of turbulent plane channels in the range $547 \leq Re_r \leq 2003$. It is found that regions of backflow are attached and their density per surface area - in wall units - is an increasing function of $Re_r$. Their size distribution along the three coordinates reveals that, even though in the mean they appear to be circular in the wall-parallel plane, they tend to become more elongated in the spanwise direction after reaching a certain height. Time-tracking of backflow regions in a $Re_r = 934$ simulation showed they convect downstream at the mean velocity corresponding to $y^+ \approx 12$, they seldom interact with other backflow events; their statistical signature extends in the streamwise direction for at least 300 wall units and they result from a complex interaction between high and low spanwise vorticity regions far beyond the viscous sublayer. This could explain why some statistical aspects of these near-wall events do not scale in viscous units; they are dependent on the $Re_r$-dependent dynamics further away from the wall.

1This research was funded in part by the Multiflow project of the European Research Council.

10:10AM H23.00011 Turbulent inflow information generation for compressible boundary layers1, GUILLERMO ARAYA, HPCVLab, U. of Puerto Rico-Mayaguez, KENNETH JANSEN, U. of Colorado-Boulder — In this study, the dynamic rescaling-recycling approach for incompressible flows (J. Fluid Mech., 670, pp. 581-605, 2011) is extended to compressible spatially-developing boundary layers (SDTBL) for turbulent inflow conditions. Since the inlet boundary layer thickness is fixed, the inlet friction velocity is computed based on a power function of the momentum thickness, where the power exponent is calculated “on the fly” according to the flow solution downstream. Thus, there is no need of an empirical correlation as in other recycling methodologies. Additionally, the Morkovin’s Strong Reynolds Analogy (SRA) is used in the rescaling process of thermal fluctuations. The methodology is validated in a suite of Direct Numerical Simulation (DNS) of isothermal Zero-Pressure Gradient (ZPG) boundary layers at a Mach number of 2.86. The Reynolds number range is approximately 400-800, based on the freestream density, momentum thickness, freestream velocity and wall viscosity. Low/high order flow statistics are compared with wind tunnel experiments from the literature. Focus is given to the assessment of wall temperature on the thermal transport phenomena and the dynamics of thermal turbulent coherent structures.

Monday, November 25, 2019 8:00AM - 10:36AM
Session H24 Bubbles: Growth, Heat Transfer and Boiling I
606 - Prashant Valluri, University of Edinburgh
8:00 AM H24.00001 Viscous growth and rebound of confined bubbles. SEBASTIEN MICHELIN, LadHyX - Ecole Polytechnique, GIACOMO GALLINO, FRANCOIS GALLAIRE, LFMI - Ecole Polytechnique Fdrale de Lausanne, ERIC LAUGA, DAMTP - University of Cambridge — In many applications (e.g. bubble-powered micro-rockets), microscopic gas bubbles nucleate and grow in close proximity with a rigid bounding surface. This has profound hydrodynamic consequences, as the bubble is geometrically constrained and must translate away from the wall as its radius increases, in order to maintain mechanical equilibrium with the non uniform hydrodynamic stresses prevalent on the interface. This dynamic process is analyzed theoretically for a spherical inflating gas bubble in a viscous fluid, focusing specifically on the drainage dynamics of the thin lubricating film separating the bubble from the wall and for bubble surfaces of different physical nature, ranging from “clean” (i.e. stress-free) to “polluted” or rigid (i.e. slip-free) interfaces. Different bubble surface conditions lead to fundamentally different behaviors: bubbles may thus drain the lubrication film monotonically or bounce off the surface before eventually draining the film. A final universal regime (i.e. for all bubble surface conditions) is finally identified.

8:13 AM H24.00002 Bubble Coalescence at the Free Surface. DANIEL SHAW, LUC DEIKE, Department of Mechanical and Aerospace Engineering, Princeton University — Bubble coalescence at a free surface occurs in our daily lives at the surface of drinks as well as at the surface of the ocean. While coalescence inside water has been largely investigated, the studies at the free surface remain scarce. In this talk, we study experimentally the coalescence of two bubbles at a free surface. Three primary regimes are identified. During an ‘attraction’ phase, the bubbles accelerate together due to the capillary distortion of the free-surface. As the bubbles draw near, the resistance provided by the fluid between them increases and slows the advancing bubbles. This ‘drainage’ regime begins when the relative velocity of the bubbles start decreasing and ends when the film is ruptured. ‘Confluence’, the third regime, is dominated by the rapid expansion of the neck separating the newly united air pockets. A balance of capillary, inertial, and viscous forces determine the dynamics of the newly-formed interface. Unlike coalescence in a bulk outer-fluid, the asymmetry created by the presence of the free surface alters previous models and presents new challenges for both measuring and modeling coalescence.

8:26 AM H24.00003 Effect of Non-Uniform Circumferential Heat Fluxes and Orientation on Microchannel Flow Boiling – A Numerical Investigation. MARIUS VERMAAK, MOHAMMAD MOGHIMI, JOSUA MEYER, University of Pretoria, KHELLIL SEFIANE, PRASHANT VALLURI, University of Edinburgh — Flow boiling in microchannels exhibits incredibly high heat transfer characteristics, which could be revolutionary for multiple industries. However, the underlying physical phenomena that cause these characteristics are not well understood, especially the 3D effects of flow boiling in non-circular channels and the influence of confinement on bubbles. In this study, single bubble growth is considered in a high aspect ratio microchannel, hydraulic diameter 909 µm and aspect ratio 10, at varying gravitational orientations with only 1 face heated. While common microchannel theory neglects gravitational effects, at large aspect ratios gravity affects the hydrothermal characteristics of the flow. In particular, if microchannels are rotated along the axial direction. Bubble behavior after nucleation and its effect on heat transfer is investigated until slug formation. This investigation found that the heat transfer characteristics of the bottom heated case are the highest. In addition, the thermofluidic interaction between two sequential slugs moving down a microchannel is also presented. The results of this study have been validated against past numerical and current experimental work, some of which is being performed at the University of Edinburgh.

8:39 AM H24.00004 Nucleation of Plasmonic Bubbles in Binary Liquids. MARVIN DETERT, Physics of Fluids Group, University of Twente, The Netherlands, BINGLIN ZENG, YULIANG WANG, Robotics Institute, School of Mechanical Engineering and Automation, Beihang University, P.R. China, HAROLD J. W. ZANDVLIET, Physics of Interfaces and Nanomaterials, MESA+ Institute for Nanotechnology, University of Twente, The Netherlands, DETLEF LOHSE, Physics of Fluids Group, Max Planck Center Twente for Complex Fluid Dynamics, University of Twente, The Netherlands — When a noble metal, plasmonic nanoparticle is immersed in a liquid and irradiated with a laser of resonant frequency, it can heat rapidly and a vapor bubble can be nucleated. Bubbles generated this way are called plasmonic bubbles and have garnered a lot of attention due to their variety of applications. We want to disentangle the effect of various control parameters, such as the boiling temperature, the heat conductivity, the latent heat of vaporization etc., by measurements via ultra-highspeed imaging. A perfect candidate for these measurements are binary liquids, because their parameters can be tuned by their composition. We show both experimentally and theoretically that the time of bubble nucleation is determined by the total amount of dissolved gas. In contrast, the maximum volume of the bubble is governed by the energy needed for vaporization. Consequently, the bubble’s nucleation time and its maximal size can be tuned by varying the corresponding liquid parameters. We envisage that our findings will not only have important consequences for current applications, but might also result in new applications.

8:52 AM H24.00005 Nucleation and Growth of a Nanobubble on Rough Surfaces. SHANTANU MAHESHWARI, Shell Technology Centre Bangalore, COR VAN KRIJNISDIJK, Shell Technology Centre Amsterdam, SUCHISMITA SANYAL, Shell Technology Centre Bangalore, ALBERT HARVEY, Shell Technology Centre Houston. We study the nucleation and growth of a nanobubble on rough surfaces using molecular dynamics simulations. A nanobubble nucleates and grows by the virtue of a heterogeneous surface reaction which results in the production of gas molecules near the surface. We study the role of surface roughness in the nucleation and growth behaviour of a nanobubble. We perform simulations at various reaction rates and surface morphology, and quantified the growth dynamics of a nanobubble. Our simulations show that after the onset of nucleation, nanobubble grows rapidly with radius following t½ behaviour followed by diffusive growth regime which is marked by t¹/³ growth behaviour. This growth behaviour remains independent of surface roughness and reaction rates over the range considered in this study. We also quantified the oversaturation of gas required for the nucleation of a nanobubble and demonstrated its dependence on the surface morphology.

9:05 AM H24.00006 Near-wall bubble expansion and jetting collapse in generalized Newtonian fluids. JONATHAN FREUND, University of Illinois at Urbana-Champaign, RATNESH SHUKLA, Indian Institute of Science — The jetting dynamics of a gas bubble near a wall in a non-Newtonian fluid are investigated using axisymmetric simulations. The bubble gas is assumed homogeneous, with density and pressure related through a polytropic equation of state. An incompressible, Eulerian-frame, Navier-Stokes solver for generalized Newtonian fluids is used, with discretization modified to sharply represent the shear-free bubble-liquid interface. Simulations show both stabilization and destabilization due to non-Newtonian effects. In general, for fixed zero- and infinite-shear-rate viscosities, shear-thinning promotes and shear-thickening suppresses jet formation and impact. For a shear-thinning fluid, a threshold Carreau time scale A is found that suppresses both jetting and impact. Likewise, for shear-thickening, a minimum is found that suppresses both. The bubble-wall speed increases sharply with shear thinning and decreases for shear thickening. However, the bubble volume is far less sensitive, changing less than 50% for 0 < λ < ∞. The general trends, and particularly the high sensitivity of the jet speed to λ, suggest a criterion that could potentially protect tissue in biomedical applications and be used for high-strain-rate, large-deformation rheology.
Bubbles and droplets with mobile surfaces bounce stronger but coalesce faster. Surfaces can lead to coalescence owing to a second collision driven by the added mass. Head-on collision of two drops, where for certain parameter regime, we counter-intuitively see a full rebound for mobile surfaces, while immobile simulations with the Gerris software using extreme local grid refinement, which can reproduce the experiments. This allows us to simulate the immobile, whereas the final coalescence takes longer. Experiments with a buoyant droplet show similar results. The stronger rebound is due to lower viscous dissipation in the intervening thin film, during the collision when the surfaces are mobile. We also perform Volume-of-Fluid simulations with the Gerris software using extreme local grid refinement, which can reproduce the experiments. This allows us to simulate the head-on collision of two drops, where for certain parameter regime, we counter-intuitively see a full rebound for mobile surfaces, while immobile surfaces can lead to coalescence owing to a second collision driven by the added mass.

A fundamental study of the channel shape impact on microchannel flow boiling via direct numerical simulations, Microchannel flow boiling is an attractive cooling solution for high-power density electronic devices. The coolant flows in a microevaporator, where many parallel channels are etched on a wafer substrate directly bonded on the surface to be refrigerated. Despite an extensive literature, there is still disagreement about the optimal shape of the channels cross-section which maximises heat transfer. Therefore, we have performed a fundamental study of the impact of the channel shape on the dynamics of elongated bubbles growing in microchannels and the associated heat transfer. We use a customised version of the Volume-Of-Fluid method in OpenFOAM, which includes a non-equilibrium evaporation model. Elongated bubbles are seeded at the upstream of a long microchannel heated with a constant heat flux. Channel aspect-ratios from 1 (square) to 8 (rectangular) are tested. We observe an essential impact of the perimetral distribution of the liquid film surrounding the bubble on the heat transfer patterns. Square channels exhibit higher heat transfer rates at low flow rates, while very thin liquid films are observed; flattened channels yield the best performance at larger flow rates, as they promote the formation of an extended liquid film covering a large fraction of the channel wall.

Optimising boiling by Surface Design from the Nanoscale Upwards. By constructing a heated surface at the molecular scale, we model the creation and growth of a bubble. In this talk, we present an introduction to MD, before showing nucleation results for a range of different surfaces. Nucleation rates are seen to depend on the details of the surface and we discuss insights provided by the MD approach. The challenge is to make these MD data relevant to larger scales, by linking these nanoscale bubbles to CFD simulations and optimising surface design to maximise nucleation. We discuss potential solutions to this problem, using multi-scale methods guided by a programme of experimental measurements.

Funding through RAEng/PETRONAS Research Chair for OKM

9:31AM H24.00008 Gravity Effects on Pool Boiling Heat Transfer. Effects of gravity on boiling heat transfer efficiency is of special interest due to its application in two-phase cooling systems for spacecraft and satellite components. Experimental investigations have identified trends in heat flux scaling that demonstrate two distinct boiling regimes dominated by buoyancy (BDB) in high gravity and surface tension (SDB) in low gravity. Regression models constructed from experimental data show that the transition between the two regimes is dependent on heater size and degree of subcooling. However, the bubble dynamics in this intermittent region are not very well understood. This serves as a motivation to identify heat flux mechanisms associated with bubble shape, size and merger using high-fidelity numerical techniques to increase scientific understanding of the process. In this talk, we will present results from our three-dimensional simulations, show a quantitative and qualitative agreement with experiments, and discuss bubble statistics that govern the scaling of heat flux in BDB, SDB and transition regimes.

Supported by NASA, Grant: NNX16AQ77G. Computational resources by NASA high-end computing program.
10:23AM H24.00012 Optimal control of the nonspherical oscillation of encapsulated microbubbles for biomedicine1, FATIH A. ARIFI, MICHAEL L. CALVISI, University of Colorado Colorado Springs — Encapsulated microbubbles (EMBs) consist of a gas core surrounded by a stabilizing shell comprised of lipid, polymer, or protein and are used for ultrasound imaging and medical therapies, such as drug and gene delivery. The nonspherical oscillation of EMBs is essential for their function as it can enhance the acoustic signature in medical imaging as well as the onset of rupture, which can affect drug/gene release. Therefore, the ability to control such oscillations can improve the efficacy of diagnosis and treatment mediated by EMBs, and reduce unwanted side effects. This talk discusses the use of optimal control theory to optimize the acoustic driving for a specific objective, such as maximizing the nonspherical subharmonic response to improve blood-tissue contrast, or exciting shape modes to incite bubble rupture or the formation of microjets, which can facilitate drug/gene uptake. These objectives are achieved through prescribing various cost functions that enhance the dynamic response of shape modes while minimizing overall acoustic energy input to improve patient safety. Single frequency, dual frequency, and broadband acoustic forcing schemes are explored and compared.

Monday, November 25, 2019 8:00AM - 10:36AM – Session H25 Minisymposium: Bubbles, Drops and Particles in Non-Newtonian Fluids 607 - Andrea Prosperetti, University of Houston

8:00AM H25.00001 Hydrodynamic interaction of a bubble pair ascending in-line in a viscoelastic liquid. ROBERTO ZENIT, Brown University — When the liquid in a bubbly flow is non Newtonian, a strong tendency to form large clusters and aggregates has been observed. In order to understand the mechanisms that lead to clustering in these liquids, we conduct experiments to determine the hydrodynamic interactions for a pair of bubbles rising in-line in a quiescent liquid. We fabricate viscoelastic fluids with shear-dependent viscosity with water-glycerin mixtures and polyacrylamide. Bubble pairs of different sizes are produced with capillaries of different inner diameters; the control of the bubble formation is achieved using a pulsatile syringe pump and a set of rapid-closing valves. The motion of bubbles is visualized with a high-speed camera. The results are contrasted with those from a Newtonian reference fluid. We observe that the interaction is significantly different from the so-called drafting-kissing-tumbling process that occurs for bubble pairs Newtonian liquids. In general, for viscoelastic fluids we observe no-kissing (how sad). Also, the bubbles do not drift apart indefinitely after interacting; instead, the bubble-pair continues to rise at a constant separation distance and angle. Furthermore, the interaction process appears to be mediated by the appearance, or not, of the negative wake behind the bubbles. Preliminary results will be shown and discussed.

8:26AM H25.00002 Particle-laden viscoelastic turbulence in channel flow1, TAMER ZAKI, AMIR ESTEGHAMATIAN, Johns Hopkins University — Individually, viscoelasticity and particles can appreciably modify channel-flow turbulence: The addition of polymers can quench the turbulent shear stress and enlarge the coherent streamwise velocity-perturbation structures; it can also cause the turbulence to cycle between an active and a hibernating state. In contrast, dilute particle concentrations can enhance the turbulent shear stress and weaken the streamwise velocity disturbances. When both viscoelasticity and the particle phase are present, the dynamics become much more intriguing as we demonstrate using direct numerical simulations of particle-laden viscoelastic turbulence in a channel. A dilute concentration (5%) of neutrally buoyant particles can aggressively amplify the cycles of hibernating and active viscoelastic turbulence. These cycles, in turn, modulate the particle migration between the channel centre and the near-wall region. Within the global dynamics is interesting micro-scale phenomenology: The particle-pair distribution function indicates that viscoelasticity leads to an exclusion corridor upstream and downstream of the particle, in the streamwise direction. An explanation is provided by contrasting the conditionally averaged fields around the particles in the Newtonian and viscoelastic conditions.

8:52AM H25.00003 Exotic shapes and microscale structure of a bubble rising in hydrophobically modified alkali-soluble emulsion polymer solutions, MATSUHIRO OHTA, Tokushima University — The motion of single air bubbles rising through 1.3 and 2.1 wt% hydrophobically modified alkali-soluble emulsion polymer (HASE) solutions are experimentally examined. As reported in past research (Ohta et. al, 2015), a bubble rising in a HASE solution will have a shape that is distinct from a bubble rising in a typical non-Newtonian fluid. A bubble rising in a HASE solution can attain a shape with a very long thin trailing edge, long branched trailing edges, blade-shaped (two-dimensional thin plate shape) trailing edges, and more. By intuition, it is predicted that these distinct bubble shapes are formed due to the contribution of the elastic effect of HASE solutions. It has been discovered experimentally that the microstructure at the trailing edge of a rising bubble is intimately related to the concentration of HASE material in the liquid surrounding a bubble and the bubble size. The various HASE induced microstructures observed are categorized: (1) herring bone, (2) fish backbone, and (3) dendritically-expanded. It is hypothesized that the determination of one of these 3 shapes cannot be explained by straightforward surface tension considerations, and instead one must investigate localized interactions between the individual polymers in a HASE solution and the gas phase in the bubble.

9:18AM H25.00004 Nonlinear physics in bubble ‘buku-buku’ process with application to quasi-periodic volcanic eruptions, MIE ICHIHARA, Earthquake Research Institute, University of Tokyo, VALRIE VIDAL, Université de Lyon, Ecole Normale Supérieure — To mimic in the laboratory the acoustic phenomena due to bubbles rising in magma, we have investigated sounds produced by successive bubbles rising through fluid in a container. In a viscous Newtonian fluid, most of the bubbles were silent, while in the non-newtonian fluid all bubbles except the first one generated sound wave at their bursting on the fluid surface. We observed a modulation pattern of the acoustic waveform through time. Moreover, we found the existence of a precursor acoustic signal previous to each bursting. The time delay between this precursor and the bursting signal is well correlated with the bursting signal frequency content. Their joint modulation through time is driven by the memory of previous bubbles, especially the presence of small satellite bubbles trapped in the fluid due to the yield stress. At volcanoes, repetitive acoustic signals with modulation are often observed as seismic or atmospheric waves, which have been interpreted as a result of changes of the system parameters. Our experimental results have pointed out a new possibility that the non-Newtonian nature of magma with its memory effect spontaneously generates such modulations.
the solvent fluid can be neglected. A conservation law balancing pressure and elastic energy permits to calculate the thread thickness exactly.

and non-linear elasticity, we derive similarity equations for the full three-dimensional axisymmetric flow field in the limit that the viscosity of the thread profile, rescaled by the thread thickness, converges to a similarity solution. Using the correspondence between viscoelastic fluids and Oldroyd-B model, we find that...
8:05AM H26.00006 Shape optimization of stirrers for mixing binary fluids, MAXIMILIAN EGGL, PETER SCHMID, Imperial College London — Mixing is an omnipresent process in a wide-range of industrial applications. It thus seems prudent to devise techniques for optimizing mixing processes under time and energy constraints. To this end, we present a computational framework based on nonlinear direct-adjoint looping for the enhancement of mixing efficiency in a binary fluid system. The governing equations consist of the nonlinear Navier-Stokes equations, complemented by an evolution equation for a passive scalar. Immersed and moving stirrers are treated by a Brinkman-penalization technique, and the full system of equations is solved using a Fourier-based pseudospectral approach. The adjoint equations provide gradient and sensitivity information which is used to improve an initial mixing strategy, based on shape, rotational and path modifications. We utilise a Fourier-based approach for parameterising and optimising the embedded stirrers and consider a variety of geometries to achieve enhanced mixing efficiency. We study a restricted optimisation space by limiting the time for mixing and the rotational velocities of all stirrers. In all cases, non-intuitive shapes produced better mixing.

9:18AM H26.00007 A minimal model for riblet geometry optimization, MITUL LUHAR, ANDREW CHAVARIN, University of Southern California — Recent work shows that the forcing-response gain for resonant modes resembling the energetic near-wall cycle is a useful predictor of overall drag reduction performance over riblets. Riblet sizes and shapes identified as being optimal in previous high-fidelity simulations and experiments are found to minimize gain for this resonant mode. Building on this observation, we develop a geometry optimization framework for streamwise constant riblets. The shape and size of the riblets is parametrized using Bezier curves. A gradient-based search algorithm is employed to identify curve parameters that minimize amplification of the near-wall mode. Unsurprisingly, this procedure identifies scalloped and blade-like geometries as being optimal. Moreover, when scaled in inner units, the optimal sizes for these geometries are found to be insensitive to Reynolds number. Preliminary optimization results that take manufacturability constraints into account are presented briefly. Physical mechanisms responsible for performance deterioration are discussed in the context of the resonant-based predictions.

9:31AM H26.00008 Solution to shape design of unsteady natural convection fields to control time history of flow velocity, EIJJI KATAMINE, National Institute of Technology, Gifu College, TAKASHI AOKI, Nagaoka university of Technology — This paper presents a numerical solution to shape design of unsteady natural convection fields to control time history of flow velocity. The square error integral between the actual time history of flow velocity and the prescribed time history of flow velocity on the prescribed sub-domain during the specified period of time is used as the objective functional. Shape gradient of the shape design problem is derived theoretically using the Lagrange multiplier method, adjoint variable method, and the formulae of the material derivative. Reshaping is carried out by the projection method presented as an approach to solving shape optimization problems. Numerical analyses program for the shape design is developed based on FreeFem++, and the validity of proposed method is confirmed by results of 2D numerical analyses.

9:44AM H26.00009 A model-based investigation of the effect of actuator geometry on boundary layer flows, Iagal Gluzman, Dennise Gayme, Johns Hopkins University — An input-output approach is used to study actuated boundary layers arising from different types of input signals and actuator geometries. We obtain the manipulated flow fields through the Navier-Stokes equations linearized about a given base flow with the spatial geometry of the actuator represented as an array of localized input sources organized in the pattern of interest. The actuated fields are then obtained by superposing the response of each localized source in the array pattern, e.g., a saw tooth plasma actuator whose signal varies in intensity over the geometry. Actuation signals including a single pulse, a train of pulses, and a continuous input are modeled through analytical solutions of the LNS system. As an example, a steady-state step response is used to reproduce the stationary actuated flow-fields due to different plasma actuator configurations in transitional boundary layers. The model is found to reproduce the vortical and streamwise velocity structures obtained in experimental and simulation studies qualitatively well. Our results demonstrate the promise of such an analytical tool in determining beneficial actuator configurations prior to detailed experimental or high fidelity simulations, which are too costly for expensive parametric studies.

9:57AM H26.00010 Adjoint-based Interfacial Control of Axisymmetric Viscous Drops, Alexandre Fikl, Daniel J. Bodony, Aerospace Department, University of Illinois at Urbana-Champaign — We develop a continuous adjoint formulation for the control of the deformation of a clean, neutrally buoyant droplet in Stokes flow. The focus is on constant surface tension-driven flows, where the interface is deformed with the local fluid velocity. We apply well-known results from the field of shape optimization to rigorously derive the optimality conditions for a wide range of interfacial problems. In the cases of interest, we make use of boundary integral methods as a natural choice for the numerical discretization of the flow variables. In the static case, our methodology is tested on several tracking-type cost functionals, corresponding to classic shape optimization problems. We show agreement with black-box finite difference-based gradients and accurate minimization of the cost functionals. Finally, we show that the methodology also applies to the control of the unsteady droplet deformation, controlled by external forcing in the form of the Capillary number.

10:10AM H26.00011 A new Drunken Sailor perspective and Spontaneously Singular Control approach for Lagrangian particles (buoyancy-controlled balloons) in highly stratified turbulence, Thomas Bewley, UCSD, Paolo Lucini, UNISA, Gianluca Meneghello, MIT — We will discuss recent progress in an ambitious project proposing a low-cost balloon observation system for sustained (in time), broadly distributed (in space), in-situ (between 1-km altitude), real-time (from data acquisition to NCAR within 20 minutes) measurement of hurricane development. The high density in space and time of measurements from such a robotic sensor vehicle swarm (100 or more vehicles persisting for 5 days) will be invaluable in improving our ability to estimate and forecast such extreme and dangerous atmospheric events. Recent work has focused on a decentralized strategy for rejecting small-scale disturbances of the sensor balloons (acting as Lagrangian tracers in the horizontal directions) that arise due to unresolved turbulent flowfield fluctuations with a concomitant $\omega^{-2}$ spectrum. This is done by modeling the balloon velocities (note: NOT positions) with a statistical random walk away from those planned by the coordinating MPC formulation. Implementing a realistic control penalty, $<|u|>$, in this setting gives a curious (and, practically implementable!) Spontaneously Singular Control strategy (on-off); this strategy is ultimately to be combined in a hierarchical setting with centralized MPC coordination of the large-scale balloon trajectories.
10:23AM H26.00012 Enhanced scalar transport through predictive reorientation of flow fields, RUUD LENSVELT, MICHEL SPEETJENS, HENK NIJMEIJER, University of Technology Eindhoven — Enhancements to scalar transport by fluid flow involves improved redistribution of heat/chemicals through advection. Improvements will be beneficial for a large span of industrial applications ranging from inline mixing in food production to subsurface resource extraction. A common feature in the applications of interest is reorientation of boundary driven laminar base flows to promote scalar transport. In conventional approaches a fixed, periodic reorientation scheme (in space or time) is optimized to accomplish chaotic advection. However, it is unclear whether such approaches produce the most effective propagation of transport in the presence of significant diffusion and/or chemical reactions. In this work, we explore an optimization scheme to predict the optimal orientation to enhance scalar transport over a certain time horizon. Spectral decomposition of the base flow allows for a compact model to ensure efficient prediction of the scalar field in this scheme. We investigate boundary heating of a cold fluid in a 2D circular domain with reorientation of the base flow based on both schemes. The optimization approach shows significant acceleration towards homogenization of the scalar field which demonstrates its potential to improve transport with reorientation of flow fields.

8:00AM H27.00001 Flapping locomotion across a water-air interface1, LEAH MENDELSON, CHRISTOPHER PANIAGUA, ETHAN GREENBERG, WING-YEE LAW, Harvey Mudd College — Inspired by jumping fish, we investigate the propulsive performance of plates and hydrofoils that are simultaneously flapping and translating vertically out of the water. Compared to fully-submerged scenarios, additional considerations in this application include reduced force production during partially-submerged movements and interactions between the propulsion and the free surface. We explore trade-offs between thrust production, stability, and splash control when the actuator is partially-submerged. In particular, we consider whether a decaying sinusoidal motion profile is a viable strategy for producing useful amounts of thrust while mitigating lateral forces throughout the water-to-air transition. We also identify factors that determine the critical time and position during the translation out of the water where no further propulsion is beneficial.

8:13AM H27.00002 Bubble PIV Measurements of Swimming Sea Lions2, GINO M. PERROTTA, THE George Washington University, FRANK E. FISH, West Chester University, MEGAN C. LEFTWICH, The George Washington University, DANIELLE S. ADAMS, West Chester University, JENIFER ZELIGS, STAFANI SKROVAN, SLEWTHS — California sea lions are among the most agile of swimming mammals. While most marine mammals swim with their hind appendages flippers or fluke, depending on the species sea lions use their foreflippers for propulsion and maneuvering. The sea lions’ propulsive stroke generates thrust by forming a jet between the flippers and the body and by dragging a starting vortex along the suction side of the flipper. Prior experiments using robotic flippers have shown these mechanisms to be possible, but no flow measurements around live sea lions previously existed with which to compare. In this work, the flow structures around swimming sea lions are observed using an adaptation of Particle Imaging Velocimetry. To accommodate the animals, it was necessary to use bubbles as seed particles and sunlight as illumination. Three trained adult California sea lions were guided to swim through an approximately-planar sheet of bubbles for a total of 173 repetitions. The captured videos were used to calculate bubble velocities, which were processed to isolate and inspect the flow velocities caused by the swimming sea lion. The methodology will be discussed and measured flow velocities will be presented.

8:26AM H27.00003 Flow Structures Generated by a Robotic Sea Lion Foreflipper, ADITYA A. KULKARNI, ELI KASHI, GINO PERROTTA, MEGAN C. LEFTWICH, The George Washington University — Unlike most biological swimmers that rely on body/caudal fin (BCF) type of locomotion, a California sea lion produces thrust by moving its large foreflippers from above its head into a position abducted against its abdomen, a motion called a clap. This is followed by a long glide in a streamlined position. The flow structures resulting from this motion will not resemble the traditionally seen structures during BCF swimming, namely the reverse von Kármán street. Here, we use particle image velocimetry (PIV) to study the flow around an anatomically correct silicone flipper that is actuated by a servo motor. The flipper is mounted on a robotic platform and is programmed to go through the motions of a sea lion clap. The resulting data indicates that thrust is not produced through compression of fluid between the ventral side of the flipper and the body. Instead, the surrounding fluid is entrained by the upper surface of the flipper, producing vortices that run along the span and directly off the tip of the flipper. We also notice a cutoff frequency after which the efficiency of velocity production diminishes, which indicates the existence of an ideal ratio between rotational velocity and tip speed.

8:39AM H27.00004 A tendon-inspired adjustable-stiffness joint improves swimming speed and efficiency, QIANG ZHONG, JIANZHONG ZHU, HILARY BART-SMITH, DANIEL QUINN, University of Virginia — Fish dynamically control muscle stiffness to improve their swimming performance. The advantages of adjustable stiffness are only partially understood, because experiments on robotic tail fins have been limited to 3 Hz or less, whereas fish and fish-inspired robots can flap their tail fins at 10-15 Hz. We present here an actuator that flaps tail fins up to 7 Hz and uses a tunable spring to precisely control the stiffness of the peduncle (tail fin joint) in real-time. Our results show that dynamic stiffness control allows tuna-like fish to maintain high efficiency over a wide range of speeds (0 – 2.5BL/s). We tested this result on a multi-speed long-distance mission (500 m) and found that controlling stiffness while swimming can reduce energy consumption. Three-dimensional Particle Image Velocimetry illustrates what wake structures are responsible for improving efficiency, particularly when peduncle stiffness is optimized at high speeds. Understanding the flow physics governing adjustable tail stiffness at high swimming speeds could guide biological hypotheses about muscle control in fish and offer design ideas for fish-inspired underwater vehicles.
8:52AM H27.00005 What do fishes and fighter jets have in common?1, DANIEL QUINN, QIANG ZHONG, HAIBO DONG, University of Virginia, SMART FLUID SYSTEMS TEAM — Multi-fin systems, like fish or fish-inspired vehicles, are governed by unsteady three-dimensional interactions between their multiple fins. In particular, dorsal/anal fins have received much attention because they are just upstream of the main thrust-producing fin: the caudal (tail) fin. We used a tuna-inspired fish model with variable fin sharpness to study the interaction between elongated dorsal/anal fins and caudal fins. We found that the performance enhancement is stronger than previously thought (15% increase in swimming speed and 50% increase in swimming economy) and is governed by a three-dimensional Dorsal Fin-induced Crossflow that lowers the angle of attack on the caudal fin and promotes spanwise flow. Both simulations and multi-layer Particle Image Velocimetry reveal that the crossflow stabilizes the Leading Edge Vortex on the caudal fin, similar to how wing strakes prevent stall during fixed-wing aircraft maneuvers. Unlike other fin-fin interactions, this mechanism is phase-insensitive and offers a simple, passive solution for flow control over oscillating propulsors. Our results offer new insights into dorsal/anal fin shape and placement in fish and fish-inspired vehicles.

9:05AM H27.00006 Aerodynamic Characteristics of Bio-Inspired Wings with Spanwise Waviness in a Turbulent Freestream, ALEXIA MARTINEZ-IBARRA, ROBERT FREEMAN, ISAAC CHOUTA-PALLI, The University of Texas - Rio Grande Valley — An experimental study is performed to investigate the effect of varying amplitude and wavelength of leading-edge tubercles on the aerodynamic and flow field characteristics of a NACA-0010 airfoil in flow with high freestream turbulence intensity of 4%. The study involved three airfoils – a smooth leading-edge, and two with a tubercle amplitude of 6% of chord, and with eight and four tubercles (varying wavelength) over the span. The aspect ratio of all airfoils was 2.0. The freestream velocities ranged from 16 to 40 m/s, with the corresponding chord-based Reynolds number varying from 160K to 412K. The angle of attack was varied from -6 to 30 degrees. The results show that the two tubercled airfoils achieved little to marginal performance enhancement pre-stall. In the post-stall regime, the lift coefficient of the longer wavelength tubercle airfoil was only marginally higher than the baseline while the smaller wavelength airfoil evinced the highest lift and delayed stall in the range of Reynolds numbers tested. The flow field data obtained using PIV showed large amount of turbulent mixing at leading edge of the tubercle airfoils, thus delaying flow separation, and leading to delayed stall as compared to the baseline airfoil.

9:18AM H27.00007 Optimal three-dimensional trajectory to generate maneuvering forces with a caudal fin of large aspect ratio, CECILIA HUERTAS-CERDEIRA, MORTEZA GHARIB, California Institute of Technology — The flapping motion of a caudal fin is an efficient method of generating thrust forces in an unmanned underwater vehicle. Simple pitching and heaving motions of this appendix, however, are not sufficient to achieve agile maneuvering of the vehicle. To address this deficiency, the use of a caudal fin that can perform large rotations around all three axes is explored. Due to the large number of possible trajectories attainable by such a mechanism, this study employs an experimental optimization procedure to obtain the most efficient three-dimensional trajectory that can generate a specified side-force value, equivalent to a turning moment. The optimal trajectory followed by a fin of large aspect ratio is presented and shown to be highly efficient. The trajectory is then experimentally analyzed in detail, and the use of fins of varying flexibility is considered, with increased flexibility being shown to be detrimental to the maneuvering performance of the fin.

9:31AM H27.00008 Swimming gait driven by proprioceptive feedback.1, JESUS SANCHEZ-RODRIGUEZ, CHRISTOPHE RAUFaste, MEDERIC ARGENTINA, UCA, CNRS, INPHYNI UMR 7010 — We have developed an elementary theoretical model of aquatic locomotion, based on [1] and [2]. We link the locomotion velocity to the kinematic of the foil. The amplitude and the beating frequency of the tail are still chosen by the swimmer and we would like to propose a simple mechanism which selects them. Here, we suppose that the tail motion proportionally depends on the normal force felt by its body. We have constructed a robotic compliant fish which is attached to a force sensor. We vary the feedback intensity and we measure the resulting thrust, amplitude and frequency. Our theoretical model accurately predicts the experimental outputs.

9:44AM H27.00009 Burst-and-coast dynamics in zebrafish and tetrafish. 2, BENJAMIN THIRIA, RAMIRO GODOY-DIANA, ESPCI, FREDERIC LECHENault, LPENS, BILL FRANCOIS, ESPCI, GEN LI, DMITRY KOLOMENSKIY, Japan Agency for Marine-Earth Science and Technology, PMMH/LPENS TEAM, PMMH/LPENS TEAM — Swimming kinematics of small fish such as zebrafish or tetrafish are characterized by intermittent sequences consisting in an “active” swimming phase directly followed by a passive “coast” phase. This work is an attempt to characterize those sequences using several archetypal model experiments and models gathering hydrodynamics, statistics and behavioral sciences. We will focus on new results obtained from real fish experiments in free swimming and forced-gait configurations (using a controlled swimming channel). We will show how the statistics of these S2D sequences evolve with the conditions of the experiment as external flow conditions size of the habitat the maturity state of the fish (larva, juvenile or adult). We believe that these results will have direct implications on the design and implementation of biomimetic robotic systems.

9:57AM H27.00010 Hydrodynamic Interaction of Pitching Hydrofoils in Close Formatio, MICHAEL BOLTRI, OSCAR CURET, Florida Atlantic University — Swimming in close formation has the potential to improve swimming performance including swimming speed or power consumption. Numerical and physical models have shown that swimmers can take advantage of vortex shedding from other swimmers. However, most of the experimental work has been limited to few swimmers and tend to focus on the hydrodynamic interaction within the school. In this work, we developed an array of nine pitching hydrofoils (NACA0025) in close formation to examine the hydrodynamic interaction within the group and the wake generated by the group of foils. The pitching foils were tested in an inclined soap film to capture the flow structures generated by the foils. The foils were pitched at the quarter-chord with either sinusoidal or triangular wave patterns. The foils were tested with different frequency, amplitude, phase difference and spacing between them. We were able to capture the hydrodynamic interaction and the flow structure generated by the group. It appears that the flow structure generated by the group of foils is the result of a recombination of the vortex structures generated by the individual foils.

10:23AM H27.00012 The role of edge curvature on the thrust force in a stingray inspired plan-form . RAVI CHAITHANYA MYSRA, PABLO VALDIVIA Y ALVARADO, Singapore University of Technology and Design — Optimizing the geometry of stingray inspired plan-forms for propulsive performance is of interest to design bio-inspired underwater vehicles and robots. Thrust generation is characterized by an exchange of momentum from plan-form to fluid as well as generation of edge vortices. Numerical simulations are performed at a Reynolds number of 500 on various geometries of the plan-form to better understand this phenomenon for a prescribed travelling wave. The plan-form surface area is kept constant while the geometry of the plan-form is varied from a rounded to a square shape by changing the curvature of the edge. As the curvature of the edge decreases, the thrust coefficient decreases. The effect of stingray inspired wave motion for various plan-form geometries with respect to thrust generation is analyzed in detail. The influence of edge curvature on the shape and strength of leading-edge vortices is characterized. The suction pressure and the generation of pressure due to exchange of momentum on the plan-form is also quantified.

Session H28 Particle laden Flows: Particle - turbulence Interactions 610 - Pedram Pak-seresht, Oregon State University

8:00AM H28.00001 Particle-laden Channel Flow with Strong Radiative Heating . JACOB WEST, SANJIVA LELE, Stanford University — In particle-based solar receivers, dense particles in a turbulent flow are radiatively heated, and in turn transfer energy to a carrier fluid via convection. When the particle mass loading and radiative heating are large enough to cause O(1) changes in carrier gas density and viscosity, this coupling introduces additional effects on the turbulence, beyond the turbulence modulation expected in isothermal two-way coupled particle-laden flows. Using a multiphysics code to solve the coupled Navier-Stokes equations, radiative transport equation, and Lagrangian particle trajectories, we perform direct numerical simulation of an irradiated channel flow at low Reynolds number, using the point particle representation. In this study, we present turbulence statistics and the turbulence kinetic energy budget for this flow at various particle mass loading and incident radiation levels. Funding support provided by US Department of Energy (DOE), Predictive Science Academic Alliance Program (PSAAP) II Center at Stanford: DE-NA-0002373

8:13AM H28.00002 Interaction between Saltating Particles and Turbulent Structures in Wall Region of Boundary Layer1 . WEI ZHU, Lanzhou University, DEPARTMENT OF MECHANICS, LANZHOU UNIVERSITY, KEY LABORATORY OF MECHANICS ON DISASTER AND ENVIRONMENTAL TEAM — Interaction between saltating particles and turbulent structures in the wall region of boundary layers was investigated through vertical 4-point measurements of wind fluctuations and sand particle counts synchronously at the Qingtu Lake Observation Array (QLOA) site. The measuring spots were positioned within the sand saltation layer at wall-normal heights of 0.15, 0.2, 0.3 and 0.5m respectively. Based on autocorrelation analysis on the spatial scale of coherent structures, the results show that saltating particles cause the streamwise length scale of coherent structures in the wall region decrease, and the effect introduced by moving particle-phase becomes more obvious as the wall-normal distance decreases. Spectrum analysis on the one-hour wind fluctuations with and without saltating particles shows that saltating particles significantly enhance small-scale turbulent fluctuations while the large-scale motions are weakened in the near wall region. These results indicate that saltating particles destroy the large-scale motions at the bottom of the logarithmic region of the atmospheric Surface Layer (ASL), which are dissipated into smaller-scale structures.

8:26AM H28.00003 Comparison of Euler-Lagrange schemes in two-way coupled particle-laden channel flow1 . JEREMY HORWITZ, GIANNLUCA IACCARINO, JOHN EATON, ALI MANI, Stanford University — Considerable recent work to advance the state-of-the-art in Euler-Lagrange modelling of particle-laden flows has focused on the development of methods to estimate the undisturbed fluid velocity. This quantity is needed to calculate the drag force, which couples the motion of particles to the fluid. Historically, the undisturbed fluid velocity was estimated as the interpolated fluid velocity at the particle location. However, this estimate can be highly inaccurate when the particle size is not small compared with the mesh size. Promising new approaches have been developed to accurately estimate the undisturbed fluid velocity at particle locations for particle sizes up to and exceeding the grid spacing. One limitation of these methodologies is that they apply strictly in unbounded settings, where the computed disturbance flow can freely decay. In wall-bounded configurations, the disturbance must decay more rapidly—to satisfy no-slip and no-penetration at solid boundaries. Though a number of existing schemes are suitable on anisotropic grid arrangements which are typical of wall-bounded flows, we demonstrate they nevertheless cannot accurately predict the undisturbed fluid velocity at all wall-normal separations. We present an alternative paradigm which can improve undisturbed fluid velocity predictions in wall-bounded environments and apply this methodology to turbulent particle-laden channel flow.

Transport and two-way coupling effect of inertial particles by large-scale and very-large-scale motions in turbulence

8:39AM H28.00004 Transport and two-way coupling effect of inertial particles by large-scale and very-large-scale motions in turbulence¹. GUOQUAN WANG, DAVID RICHTER, University of Notre Dame — Direct numerical simulations two-way coupled with inertial particles are used to investigate the particle distribution and two-way coupling effects associated with the large-scale motions (LSMs) and very-large-scale motions (VLSMs) in a channel flow at a moderate Reynolds number. One method of filtering the VLSMs from the flow is via artificial domain truncation, which alters the mean particle concentration profile and particle clustering due to the removal of VLSMs from a large domain simulation. In order to exclude possible correlation of the turbulence introduced by a small domain size with periodic boundary conditions, low- and high-pass filtering is performed during the simulation to isolate the particle interaction with different spatial scales. The particle interactions with different spatial scales are underpredicted without VLSMs, whereas the particle clustering and two-way coupling effects are mainly determined by particle coupling with LSMs. In the inner layer, the elongated streamwise anisotropic particle clustering can be reproduced by particles coupling solely with LSMs for low Stokes number particles. However, we do not observe similar particle clustering behavior in the outer layer as seen in the full simulation.

Characterization of Inertial Particles in Turbulent Axisymmetric Wakes of a Porous Disk

8:52AM H28.00005 Characterization of Inertial Particles in Turbulent Axisymmetric Wakes of a Porous Disk. KRISTIN TRAVIS, SARAH E. SMITH, Portland State University, MICKAL BOURGOIN, ENS Lyon, HENDA DJERIDI, LEGI - Laboratoire des coulements Gophysiques et Industriels, RAL BAYON CAL, Portland State University, MARTIN OBLIGADO, LEGI - Laboratoire des coulements Gophysiques et Industriels. — Previous studies have suggested that dense particles such as dust and precipitation affect wind turbine performance. This study investigates the effects of micrometric inertial particles in the turbulent axisymmetric wake behind a stationary porous disk in a wind tunnel. Recent studies have explored turbulent wakes of stationary porous disks as analogs to the wakes of moving rotors yet inertial particles have not been considered. Phase Doppler interferometry and particle image velocimetry were implemented in the near wake of the turbulent wake to study the entrainment of inertial particles (mean diameter of 60μm) with a mean diameter of 60m). Reynolds numbers and water volume fractions were tested over ranges [Req (17.7 × 10^3 – 98.6 × 10^3)] and [Dv (3.9 × 10^-6 – 2.6 × 10^-5)] respectively. Results on the size distribution of particles within the wake, their settling velocity and the preferential concentration are discussed, showing a complex dynamics of such particles, as small particles are entrained and trapped in the near wake.

The role of discrete and carrier phase mechanical coupling in the inertial particles settling velocity

9:05AM H28.00006 The role of discrete and carrier phase mechanical coupling in the inertial particles settling velocity. DANIEL ODENS MORA, Universite Grenoble Alpes, CNRS, Grenoble-INP, LEGI, F-38000, Grenoble, France, and Department of Mechanical Engineering, University of Washington, MARTIN OBLIGADO. — Inertial particles settling velocity plays a non-negligible role in several environmental, industrial and biomedical applications, such as cloud formation and pollutant dispersion.

In this study, we have recorded via Laser Doppler Interferometry the vertical and horizontal velocities of sub-kolmogorov particles in a wind tunnel facility. We have explored a wide range of Taylor Reynolds numbers (between 40 and 650) by means of an active (actuated in two different modes), and a classical passive grid. We were able to estimate the turbulence modulation coming from the inertial particles presence with the help of a recent method proposed in the literature. The particle settling velocity data recorded for the different grids tested seems to better collapse when the turbulence modulation by the particles is included into the scalings.

Pair dispersions of particles during turbulence transition

9:18AM H28.00007 Pair dispersions of particles during turbulence transition. CHUNG-MIN LEE, California State University, Long Beach, ARMANN CYLFASON, Reykjavik University, FEDERICO TOSCHI, Eindhoven University of Technology — Small passive and inertial particles are present in a variety of natural or engineering flows, and their transportation and mixing by multi-scale turbulence is both of theoretical interest and practical importance. In many natural and industrial environments, however, the turbulent flow is in a transient state, as a prototype system, we investigate the transition from isotropic to anisotropic turbulence by looking at the influence of a transitioning turbulent flow on the statistical representation of the dynamics of the particles, and compare with results from homogeneous and isotropic flows. We conduct Direct Numerical Simulations of initially homogeneous turbulence, on which we suddenly impose a mean shear. The flows are initially seeded with passive and inertial particles, assumed of size that is sufficiently small and at sufficiently low seeding density so that their effect on the turbulent flow field can be neglected, and inter-particle dynamics can be ignored. Our interest is in the feedback forces exerted by particles and is damped further with increasing inertia of particles, that is, with increasing scales of particle motions.

In this study, we have recorded via Laser Doppler Interferometry the vertical and horizontal velocities of sub-kolmogorov particles in a wind tunnel facility. Recent studies have explored turbulent wakes of stationary porous disks as analogs to the wakes of moving rotors yet inertial particles have not been considered. Phase Doppler interferometry and particle image velocimetry were implemented in the near wake of the turbulent wake to study the entrainment of inertial particles (mean diameter of 60μm) with a mean diameter of 60m). Reynolds numbers and water volume fractions were tested over ranges [Req (17.7 × 10^3 – 98.6 × 10^3)] and [Dv (3.9 × 10^-6 – 2.6 × 10^-5)] respectively. Results on the size distribution of particles within the wake, their settling velocity and the preferential concentration are discussed, showing a complex dynamics of such particles, as small particles are entrained and trapped in the near wake.

A correction scheme for two-way coupled Euler-Lagrange wall-bounded flows

9:31AM H28.00008 A correction scheme for two-way coupled Euler-Lagrange wall-bounded flows. PEDRAM PAKSERESHT, Oregon State University, MAHDI ESMAILY, Cornell University, SOURABH V. APTE, Oregon State University — The accuracy of Euler-Lagrange point-particle methods in predicting the drag force reduces when the two phases are two-way coupled owing to the disturbance created by the point-particle force on the background fluid flow. Such disturbance produces an error since the drag closure models often rely on the slip velocity computed based on the undisturbed fluid velocity, which is not readily available. Recently, few approaches have been developed for unbounded flows only, where the disturbance field is not influenced by the no-slip boundary condition on walls. In this work, the correction scheme introduced by Esmaily & Horwitz (JCP, 2018) is extended to wall-bounded flows. It is shown that the newly developed model is generic for all types of flows with and without wall boundaries. The model is tested for a particle settling in a quiescent flow parallel to the wall at different wall distances. It is shown that ignoring the wall effects on correcting the disturbed velocity results in under prediction of settling velocity that is on the same order of magnitude of the lift force. We are able to estimate the turbulence modulation coming from the inertial particles presence with the help of a recent method proposed in the literature. The particle settling velocity data recorded for the different grids tested seems to better collapse when the turbulence modulation by the particles is included into the scalings.
Particle-turbulence and particle-wall interactions in a turbulent boundary layer

9:57AM H28.00010  YI HUI TEE, ELLEN LONGMIRE, University of Minnesota — The motions of finite-size spheres moving in a turbulent boundary layer are affected by both wall friction and coherent structures. 3D particle tracking experiments conducted at Re = 700 and 1300 with sphere diameters of 60 and 120 viscous units revealed two distinct sphere behaviors dependent on density ratio. Spheres held stationary on the wall with a density ratio of 1.03 always lifted off once released, translated without rotating, and subsequently fell back toward the wall. After the spheres had accelerated significantly, lift-off events with height larger than those following the initial lift-offs were observed frequently. These subsequent lift-off events are attributed to coherent structures in the flow. By contrast, spheres with a density ratio of 1.15 did not lift off initially, but slid along the wall once released. Further downstream, these spheres developed forward rotation as well as significant rotation about the wall-normal axis, and coincidently experienced repeated weak lift-offs. Wall friction was crucial in impeding the sphere acceleration as well as in helping initiate rotation. In the talk, PIV results on surrounding flow fields will be used to help explain the various particle-turbulence and particle-wall interactions.

Two-Phase Measurements Of Small Inertial Particles In High-Re Turbulent Boundary Layers

10:10AM H28.00011  TIM BERK, FILIPPO COLETTI, University of Minnesota — The interaction of small inertial particles with a turbulent boundary layer is of importance in a wealth of physical phenomena, e.g., transport of particles in the atmospheric boundary layer as well as industrial and biological applications. Our in-depth understanding is thwarted by the lack of comprehensive experiments. Here we perform two-phase measurements of microscopic inertial particles in high-Re turbulent boundary layers. Particles are injected in the boundary layer in the one-way coupled regime. Flow field measurements (PIV) and tracking of inertial particles (PTV) are performed simultaneously. This enables conditioned evaluation of fluid velocity at and around the inertial particles. The conditionally averaged flow around particles indicates the preferential sampling of specific flow structures by the inertial particles. This preferential sampling can help explain deviation of streamwise particle velocity from the mean fluid velocity and deviation of vertical particle velocity from the Stokes settling velocity. The fluid velocity at the particle location is an important term in, e.g., the advection-diffusion equation. Moreover, using the simultaneous two-phase measurements, widespread assumptions for estimating the concentration profile can be critically evaluated.

On the physical mechanism of the two-way interaction between polymers and near-wall turbulence

10:23AM H28.00012  JUNGHOON LEE, CHANGHOON LEE, Yonsei University — The two-way interaction between polymers and near-wall turbulence was investigated through direct numerical simulations (DNS) of turbulent channel flow coupled with Brownian dynamics simulations. The finitely extensible nonlinear elastic (FENE) dumbbell model was used to describe the motion of polymer molecules. The effect of polymers was included in the Navier-Stokes equations by exerting their reaction forces back on the fluid at the nearby eight grid points via a projection technique. In our simulations, the maximum extension of the FENE dumbbells does not exceed 0.6 in wall units, which is 100 times their equilibrium length. We examine how the polymer feedback forces affect the fluctuating motion of the fluid in coherent near-wall turbulent structures for various polymer relaxation times. Our results are generally consistent with previous DNS studies based on a continuum approach. We provide a more detailed picture of the physical mechanisms for turbulence modification by polymers through investigation on polymer stretch and orientation in the Lagrangian frame.

Towards Gamified Learning in Immersive Teaching of Fluid Mechanics

8:13AM H29.00002  NITESH BHATIA, Imperial College London, KAILYN BRYK, EVELYN SALAZAR, MIT, CHARLES RIGBY, OMAR MATAR, Imperial College London — FluidsVR is designed as a Virtual Reality (VR) platform for the exploration of transient and three-dimensional (3D) phenomena to promote deeper understanding of fluid mechanics. The platform serves as a learning medium by providing accurate and interactive models to the students based on the 3D data assets generated in-house by computational fluid mechanics researchers in the Matar Fluids Group. Students can visualize and interact with these assets using an intuitive graphical-user-interface. For improving the students’ affective domain, learning outcomes, and engagement levels, we are exploring the effectiveness of gamification in the context of teaching and learning. We have arranged the data assets in the increasing order of learning complexity and incorporated game mechanisms such as interactive questions, progress levels, scores and leader-boards to motivate students to further engagement and higher achievement. In this talk, we will cover this new gamification system for FluidsVR that was developed with the help of a group of undergraduate chemical engineering research students from Imperial and MIT.

3D+time flow visualization in virtual reality

8:00AM H29.00001  MELISSA GREEN, ZACKARY BOONE, Syracuse University — By viewing fluid dynamic isosurfaces in virtual reality (VR), issues associated with the rendering of three-dimensional objects on a two-dimensional screen can be addressed. In addition, viewing a variety of unsteady 3D data sets in VR opens up novel opportunities for education and community outreach. In this work, the vortex wake of a bio-inspired pitching panel is visualised using a three-dimensional structural model of Q-criterion isosurfaces rendered in virtual reality using the HTC Vive. Utilizing the Unity cross-platform gaming engine, a program can be developed to allow the user to “scroll” forward and backward in time to analyze the formation and shedding of vortices in the wake. The user can also toggle between different quantities, while keeping the time step constant, to analyze flow parameter relationships at specific times during flow development. In the current status of the game, all of the isosurfaces are rendered as objects to import, and all the relevant isosurface objects do need to be generated externally. There exists a great potential, however, to create a dynamic platform for an interactive and immersive research and education experience using off the shelf gaming systems. As part of this talk, we hope to provide a live demonstration with an HTC Vive.

Towards Gamified Learning in Immersive Teaching of Fluid Mechanics

8:13AM H29.00002  NITESH BHATIA, Imperial College London, KAILYN BRYK, EVELYN SALAZAR, MIT, CHARLES RIGBY, OMAR MATAR, Imperial College London — FluidsVR is designed as a Virtual Reality (VR) platform for the exploration of transient and three-dimensional (3D) phenomena to promote deeper understanding of fluid mechanics. The platform serves as a learning medium by providing accurate and interactive models to the students based on the 3D data assets generated in-house by computational fluid mechanics researchers in the Matar Fluids Group. 8:26AM H29.00003 Use of Multi-sensory Immersive Technologies in Fluid Dynamics Education
LORENZO PICINALI, LYES KAHOUADJI, LACHLAN MASON, MARK SUTTON, NITESH BHATIA, ANDRIUS PATA-PAS, OMAR MATAR, Imperial College London — We present the recent virtual reality (VR) environment used in the Department of Chemical Engineering, Imperial College London, where both undergraduate and Masters-level students are able to "dive inside many classical examples of fluid mechanics (including Poiseuille flow, flow past a sphere [and associated vortex formation in the wake region], rising spherical-cap bubble, turbulent channel flow, and two-phase mixing in a stirred vessel) and explore the underlying physics. Three-dimensional CFD simulations are carried out to generate the flow field data for each flow, which are then imported into the VR. All physical fields from the CFD simulations, such as the magnitude of the velocity and stress components, as well as the pressure, are implemented in the VR environment via a sonification process where students are able to visualise and listen to chosen fields simultaneously. Our hypothesis is that this multi-sensory experience promotes a deeper understanding of the four-dimensional concepts underlying fluid dynamics.

8:39AM H29.00004 Conveying principles of fluid mechanics... through dance
JESSE CAPECELATRO, University of Michigan — Fluid mechanics is typically introduced to undergraduate engineering/physics students in their junior year, relying on knowledge from core courses in calculus and physics. Topics are traditionally introduced through tedious derivations that sometimes lack a clear conceptual interpretation. However, fluid mechanics is extremely visual, and visual solutions to classic fluid mechanics problems are highly aesthetic (for example, an oscillating wake past an obstacle, the swirl of a vortex, the chaotic motion of turbulence). In this talk, I will present an attempt at using dance to demonstrate fundamental principles of fluid mechanics. The objective is to create a visual demonstration of flow around a cylinder through a physics-constrained dance improvisation. This project involves a collaboration between Prof Capecelatro from the University of Michigan (UM) and dancers from the UM School of Music, Theatre & Dance. A series of dances were choreographed and filmed ranging from low Reynolds number (creeping) flow to high Reynolds number turbulence and inviscid (potential) flow. Details on the process and outcome of this collaborative effort will be presented, in addition to efforts to assess impact on student learning.

8:52AM H29.00005 Improving Scientific Visuals
NICOLE SHARP, Sharp Science Communications Consulting, LLC — There's truth to the old adage that a picture’s worth a thousand words. A well-designed visual can summarize your work, encapsulate an argument, or even draw media attention. Whether your research lends itself to exciting supplementary videos or your papers are made up mostly of graphical figures, it’s worth the effort to make your visuals as clean, understandable, and engaging as possible. This presentation focuses on what makes a good graphic and shares resources for improving your scientific visuals.

9:05AM H29.00006 Design and Development of Escape Room Based Interventions for Fluid Mechanics Courses
VRISHANK RAGHAV, MICHAEL MELNICK, Department of Aerospace Engineering, Auburn University — A new educational intervention tool based on the concept of escape rooms was designed and developed at Auburn University for use in the fundamentals of aerodynamics course. The details of the design for both conceptual and quantitative parts of the syllabi are discussed. The interventions consist of group-based and collaborative activities that could lead to a deeper level of engagement and understanding of fluid mechanics at the undergraduate level. The pilot implementation of these new tools and the re-design for different levels of undergraduate education and high-school outreach will be discussed.

9:18AM H29.00007 Using Coffee to Teach Fluid Dynamics
WILLIAM RISTENPART, University of California Davis — Fluid dynamics courses at the undergraduate level typically require a full year of calculus and physics as prerequisites. Accordingly, it is typically considered difficult to teach either first-year students or non-STEM (general education) students much about fluid dynamics. In this talk, we describe how brewing coffee serves as an engaging and hands-on introduction to fluid dynamics for students who have no calculus or physics background. Specifically, we use an AeroPress coffee brewer to introduce Darcy’s law and the key concepts of pressure drop, flow rate, viscosity, and permeability. Students apply a pressure by hand to a brewer placed on a standard bathroom scale, while simultaneously measuring the average flow rate out of the brewer. Measuring the thickness \( L \) of the spent moist grounds allows students to plot the flow rate versus the applied pressure drop \( P/L \) for different applied pressures and/or coffee masses, typically yielding a nice linear trend. Experiments with different grind sizes allows the impact of permeability to be explored quantitatively by linear regression. Importantly, the students can also taste the impact of the flow rate on the sensory qualities of the resulting brew, providing a memorable and highly caffeinated learning experience.

9:31AM H29.00008 Developing a New CFD Course Based on Open Source Tools: Design Experience and Student Outcomes
DEBANJAN MUKHERJEE, University of Colorado Boulder — Computational fluid dynamics (CFD) education comprises a fundamental component in training modern engineering students. CFD educators commonly explore fundamental aspects of the underlying methodology in conjunction with hands-on experience in using CFD techniques via commercial packages and tools. In addition to the (often significant) associated costs and hardware/system requirements associated with these tools, striking the right level of exposure to the intricacies behind these packages becomes critical to avoid student perception of these tools as a black box. Harnessing the open source wave provides a suitable alternative, enabling greater exposure to the underlying methods while providing the valuable hands-on simulation experience. However, integration of open source tools into educational components requires careful design considerations. We recently developed a new CFD technical elective in the mechanical engineering curriculum at the University of Colorado Boulder. Our course was successfully developed entirely based on open-source software tools and components. The class was composed of graduate and senior undergraduate students. Here we will share our experience designing the course, examples of student projects, and student learning outcomes.
Projects in Fluids Courses Made Easy (for You)  
JEAN HERTZBERG, University of Colorado Boulder — Projects can provide a number of significant benefits to students in fluids courses at both the graduate and undergraduate levels, but they can be difficult to implement, particularly in large class sections. A major problem is assessment of written project reports, which is very time consuming. Solutions include assigning projects to small teams, formed automatically by CATME.org based on student schedules. This also alleviates the #1 student objection to team projects: scheduling. Other demographics can be used in team formation to ensure inclusiveness. Students are also fearful of the unknown time requirements of a project. A scaffolding approach, breaking the project into small pieces, due at intervals through the semester helps students gain confidence and avoid procrastination. A detailed rubric is essential; it clearly states your expectations and provides a guide to assessment, allowing peer evaluation, the other essential ingredient that saves your time. Peer evaluation must be supported by class time spent on teaching constructive criticism. Anonymous peer evaluation is supported in learning management systems such as Canvas. Automatic plagiarism detection (Turnitin.com) prevents re-use of previous reports, and can be used to teach proper citation behavior. Allowing students to select their own project topics (from a list at least) promotes improved attitudes towards fluid mechanics, including the relevance of fluid physics in their daily lives.

Teardowns: students’ ability to identify components in actual systems  
MARIA-ISABEL CARNASCIALI, University of New Haven — The typical sequence of thermo-fluids related courses within mechanical engineering programs involves a thermodynamics, a fluid dynamics, and a heat transfer course. In most instances, these are accompanied by a lab component or supplemented with a separate lab. The intent of these hands-on courses (or supplements) is to broaden exposure to physical components and systems among several other learning outcomes. Students’ ability to make connections between the concepts presented in the various thermo-fluid courses and the physical parts/components with which they interact are essential to their long-term ability to function as engineers. However, these physical examples of system implementation represent but a limited view into the large variations that are currently present in and use in industry. Providing small, manageable components for students to investigate students’ ability to identify individual components but also intended purpose of the component within the system. Participants were asked to draft concept maps and system diagrams for a selected item; then proceeded to teardown the item. Participants included those who had and had not completed the lab component. Results provide insight to gaps in students knowledge and reinforce the need to show real systems as opposed to relying on system schematics or sketches.

The secret life of fluid dynamics in the patent world  
ISMAIL HAMEDUDDIN, Norton-Rose-Fulbright — A significant proportion of technical knowledge is only to be found in patent publications (80 percent of all technical knowledge, by some accounts). Fluid dynamics, often viewed as an abstruse discipline, has a significant and visible life in the patent world, with an entire CPC subclass devoted to it. On the other hand, scientific journals are replete with examples of well-meaning academics giving away perfectly patentable ideas, often to be trivially commercialized by others for unseemly gains. The patent literature is complementary, rather than an alternative, to peer-reviewed publications and is a tremendous resource for 21st century academics; it can be instrumental for sparking creativity, generating ideas for proposals, and for an insider look into the industrial/commercial applications and relevance of fluid dynamics. It may also be useful in battling fatalistic resignation among aspiring academics, which is often inadvertently induced by the well-meaning Clay Math Institute. The expense of obtaining (or even filing) a patent generally ensures the expression of commercially useful ideas in patent publications, even if they may not be expressed in the most articulate and persuasive manner.

Science Communication and Community: Entry Points to the Physical Sciences  
FRANCESCA BERNARDI, Florida State University, KATRINA MORGAN, Northwestern University — Students from underrepresented groups face numerous barriers of entry in STEM, especially in the hard sciences. Fostering a community of young people who are interested in science, but do not necessarily see themselves as possible scientists, can help them feel welcome in these fields and help build their confidence. Outreach events aligning science communication with scientific disciplines can be a point of entry for such students, who often find events with a communication aspect to be less intimidating than those focused exclusively on science activities. Incorporating communication aspects in science outreach serves several purposes: It encourages the participation of non-traditional STEM students by building a community of young people passionate about science and communicating it to the public; it helps educate these students to become better scientists, teaching them communication skills as well as challenging STEM topics; and it shows them the importance of focusing on both aspects. Experiences will be reported from Girls Talk Math, a free day camp for female and gender non-conforming high-schoolers focused on Mathematics, Physics, and media.
8:52AM H30.00003 From Depicting to Deploying Fluids in Art. ANDRZEJ HERCZYNSKI, Boston College — Water appears in ancient Greek and Roman art, on vases, in frescoes, and in mosaics of swimming fish or boats moving across the sea by oar or sail. Beginning in the Middle Ages, images of water in motion, waves, waterfalls, and wine or milk pouring from vessels, appear in landscapes and domestic scenes. Italian and Flemish Renaissance masters endeavored to render nature with the utmost attention to detail and were able, when their subject called for it, to capture fluid dynamics with astonishing precision. Including fluid effects has also allowed artists to convey motion in the static medium of painting or sculpture. Nevertheless, convincing representation of liquid flows, especially oscillatory or turbulent, has remained a challenge. The invention of non-figurative art proved liberating, leading Abstract Expressionist painters to adopt fluid phenomena themselves – jets, drips, sprays, and instabilities of liquid pigment – in the creative process. This talk offers a brief review of the quest to naturalistically depict fluids, and the alternative tactic of modern artists who learned to deploy fluids, endowing their abstractions with nature’s own patterns.

9:18AM H30.00004 Pattern formation in watercolor paintings. JORGE GONZALEZ-GUTIERREZ, Facultad de Ingeniería-Universidad Nacional Autónoma de México — The restoration of a masterpiece is essential to preserve its historical and commercial value. With the aim to find physical laws that allow us to predict the complex phenomena that emerge during the materialization of artistic work, we explore on the effect of the pigment concentration and paper humidity on the pattern formation driven by evaporation of droplets of watercolor paintings. These control parameters induce the formation of color gradients, stratifications, flat regions, borders, dendritic shapes, and radial tips. Interestingly, the droplet evaporation on dry paper form coffee rings stains regardless of the nature of the pigment. The mean pixel intensity of such stains follows an exponential function that saturates at high concentration, while the thickness of the coffee ring increase for watercolor inks containing colloidal particles and does not change for non-colloidal. The experiments reveal that water distribution on the paper surface, and not on the density of water on the paper, determine the structural characteristics of watercolor stains. We show evidence that the cornerstone in the creation of complex patterns in watercolor paintings is driven by the coffee ring effect and imbibition processes. Our findings could help with the correct application of restoration processes to preserve the heritage value of watercolor artwork.

9:31AM H31.00001 Geometry and Hydrodynamics of Flagellar Bundles1. MÁRIA TATULEA-CODREAN, ERIC LAUGA, DAMTP, University of Cambridge — Most motile bacteria exploit chirality in order to break the symmetry of low Reynolds number flows and generate propulsion. Spirochaetes have developed corkscrew-shaped bodies, while bacteria with simpler bodies can assemble and actuate helical flagellar filaments. In the case of multi-flagellated species, the bacterium can bundle and unbundle its flagellar filaments in order to swim in a straight line or change direction, respectively. This process is central to their run-and-tumble mobility. The hydrodynamic benefit of having multiple filaments, however, is associated with an increasing risk of tangling within the bundle. At one extreme, we know that straight flagellar filaments could not intertwine, but neither could they propel the cell forward in a viscous fluid. Similarly, one filament could never tangle on its own, but neither could it generate a propulsive force as large as a bundle of flagellar filaments. In this talk, we will present some recent theoretical results about the role that flagellar geometry and number play in the robustness of forming a tangle-free bundle and the hydrodynamic efficiency thereof.

1We gratefully acknowledge funding from the George and Lillian Schiff Foundation (award to MTC) and the European Research Council under the European Union’s Horizon 2020 research and innovation programme (grant agreement 682754 to EL).

Monday, November 25, 2019 8:00AM - 10:36AM – Session H31 Biological Fluid Dynamics: Locomotion Flagella 613 - Henry Fu, University of Utah

8:00AM H31.00001 Geometry and Hydrodynamics of Flagellar Bundles1. MÁRIA TATULEA-CODREAN, ERIC LAUGA, DAMTP, University of Cambridge — Most motile bacteria exploit chirality in order to break the symmetry of low Reynolds number flows and generate propulsion. Spirochaetes have developed corkscrew-shaped bodies, while bacteria with simpler bodies can assemble and actuate helical flagellar filaments. In the case of multi-flagellated species, the bacterium can bundle and unbundle its flagellar filaments in order to swim in a straight line or change direction, respectively. This process is central to their run-and-tumble mobility. The hydrodynamic benefit of having multiple filaments, however, is associated with an increasing risk of tangling within the bundle. 8:13AM H31.00002 Synchronization modes of active microfilaments. YI MAN, EVA KANSO, University of Southern California — Biological filaments are rarely found in isolation. Eukaryotic flagella beat in synchrony, an array of cilia generate the phase-locking metachronal wave. Experimental and computational studies provide a body of evidence that active filaments can synchronize through hydrodynamic coupling only. Previous theoretical models mostly address interactions in a far-field regime, where the interfilamentous distance h is much larger than the filament length L. Here, we employ a simple active filament model and combine it with an asymptotic result of hydrodynamic interactions in a more biologically-relevant regime where h/L ≪ 1. By varying the activity and coupling strength, we find three synchronization modes: in-phase, anti-phase, and a new mode which we refer to as asymmetric synchronization. We map the basins of attraction of these modes and find bistable in-phase and anti-phase synchronization when the coupling is strong. Furthermore, we present a thorough Floquet-type stability analysis to show the evolution of the phase difference between two filaments. The Floquet analysis proves the existence of the new mode of asymmetric synchronization, and it reveals a time scale it takes to reach the synchronized equilibria.
8:26AM H31.00003 How do colonial micro-algae swim towards light? , HELENE DE MALEPRADE, University of Cambridge, FREDERIC MOISY, Paris-Sud University, TAKUJI ISHIKAWA, Tohoku University, RAYMOND E. GOLDSTEIN, University of Cambridge — Microscopic algae are commonly found in mud, puddles or lakes, and show great diversity in structural complexity. One of the simplest algae encountered is the unicellular ‘Chlamydomonas’, exhibiting two flagella whose beating enables them to swim in a breast stroke. One also finds ‘Gonium pectorale’, a colony made of 16 Chlamydomonas-like cells arranged in two concentric squares, with all flagella on one side of the plate. These colonies are among the first multicellular algae and their study offers an insight into the evolution from unicellular to coherent multicellular behaviour. Algae, like plants, get energy from photosynthesis: Gonium colonies take advantage of their motility to swim towards light, efficiently reorienting within a couple of seconds. However, the mechanism of this phototactic behaviour is not yet understood: how do all 16 cells individually produce a coherent collective response? How are the flagella modulated to create an asymmetry in the swimming pattern, and how does that lead to reorientation? We experimentally investigate the phototaxis of Gonium, analysing their reorientation trajectory towards light. We compare those results to an analytical model and numerical simulations, describing with high precision the reorientation process.

8:39AM H31.00004 Bending Stiffness and Critical Forces for Polymorphic Transformations of Salmonella Flagella Measured in a Microfluidic Channel , HOSSEIN MOGHIMIFAR, Department of Mechanical Engineering, University of Utah — Bacterial flagella are internally-driven flexible filaments that display complex beating patterns. We develop a method to reconstruct the 3D geometry of a bacterial flagellum from fluorescence microscopy images with sub-pixel accuracy. The flagellar geometry is specified as a helix with pitch, radius, and axis direction that vary along its length. The expected image of the geometry is generated using point spread function. For each flow rate, we find the best-fit flagellar geometry by minimizing the pixel-to-pixel intensity difference between the generated and the microscopic image using a genetic algorithm. From the geometry of the flagellum and the known flow in the microchannel, we determined the forces on the flagellum using a boundary element method and found the critical force that caused the transformation. We also use a Kirchoff rod model to find the bending stiffness of the flagellum.

8:52AM H31.00005 Time-dependent hook flexibilities in run-reverse-flick motility, MEHDI JABBARZADEH, HENRY C. FU, University of Utah — The deformation of the hook and flagellum affects bacterial motility in run-reverse-flick motility of single-flagellated bacteria. Previously, we have modeled the initiation of a flick, in which the flagellum makes a large off-axis motion, by an efficient linear spring model with a rigid cell body and flagellum while neglecting hydrodynamic interactions between the cell body and flagellum. However, a complete flick event involves bending of both the hook and flagellum as well as a time-varying hook stiffness. Here, we study the dynamic bending of the hook and flagellar filament during run-reverse and flick motility of single flagellated bacteria. We develop an accurate and more efficient numerical approach to model the dynamics of free-swimming bacteria that includes flexibility of both the hook and flagellum. Using numerical models, we are able to constrain the time-dependent flexibility of the hook during run-reverse-flick motility. We compare results from rigid body simulations to the flexible flagellar filaments. Finally, we simulate complete flick events, investigating the buckling angle and reorientations of the swimming cells due to time-dependent hook stiffness.

9:05AM H31.00006 Hook flexibility and body trajectories of swimming microorganisms, ZONGHAO ZOU, WILSON LOUGH, SAVERIO SPAGNOLIE, University of Wisconsin-Madison — The flexibility of the hook connecting the bacterial flagellum to the cell body, and an associated buckling instability, is believed to play an important role in microorganism locomotion. We consider a simplified model for the flagellum-cell dynamics and solve analytically for the flagellum orientation and cell trajectory through space. This hook flexibility affects the swimming path of the cell body and flagella. We solve the problem for different geometries and cell velocities. We show that the model can reproduce key features of the swimming paths for a wide range of parameters. We also consider the effect of cell stiffness on the swimming paths and show that the cell stiffness can significantly affect the swimming dynamics. Our results provide insights into the role of hook flexibility in microorganism locomotion and suggest new experimental methods to study the role of hook flexibility in swimming.

9:18AM H31.00007 ABSTRACT WITHDRAWN —

9:31AM H31.00008 Estimation of Internal Power Distribution in Sperm Flagella from Measurements of Beat Patterns , ASHWIN NANDAGIRI, IIITB-Monash Research Academy, India, AVINASH GAIKWAD, School of Biological Sciences, Monash University, Australia, DAVID POTTER, Monash Microscopy Institute, Monash University, Australia, JULIO SORIA, Department of Mechanical & Aerospace Engineering, Monash University, Australia, MOIRA OBRYAN, School of Biological Sciences, Monash University, Australia, SAMEER JADHAV, Department of Chemical Engineering, Indian Institute of Technology Bombay, India, RANGANATHAN PRABHAKAR, Department of Mechanical & Aerospace Engineering, Monash University, Australia — Sperm flagella are internally-driven flexible filaments that display complex beating patterns. We estimate energetics of the internal driving from measurements of beat patterns. A large number of beat cycles (40) of mouse sperm tethered at their heads are recorded using high-speed, high-resolution microscopy. Flagellar centrelines are digitally extracted using image processing techniques. Proper Orthogonal Decomposition (POD) is used to represent the beat cycle data in a compact form and obtain an average representative beat cycle. The Kirchhoff theory for inextensible, elastic, rods is adapted to account for internal driving and combined with the Resistive Force Theory for hydrodynamic forces to compute the spatiotemporal power distribution of the internal forces exerted by protein motors in the sperm axoneme. Representative beat patterns and internal power distributions are computed for a large number of sperm samples from mutant mice deficient in a family of proteins that regulate calcium ion flux in the flagellum. Clear differences in beat patterns are observed which are found to be correlated with the active power distribution.
velocities of single cells and colonies for different prey sizes and initial positions to compare their feeding performance. The presence of background flow affects the sperm trajectory and hence the success rate of fertilization. We have studied the effect of unbounded simple shear flow and Poiseuille flow on the sperm trajectory. The sperm moves on an elliptical trajectory in the reference frame advecting with the local background flow in the simple shear flow and the length of the major-axis of this elliptical trajectory decreases with the shear rate. In the presence of Poiseuille flow, the sperm moves downstream or upstream depending on the flow strength. The sperm also moves toward the centerline in a Poiseuille flow. The cross-stream migration velocity of sperm decreases as the transverse distance of the sperm from the centerline decreases in the close vicinity of the centerline, while it increases far away from the centerline. We use sperm number, a dimensionless number representing the ratio of viscous force to elastic force, to study the effect of flagellar flexibility on the sperm trajectory. The length of the major axis of the elliptical trajectories increases with the sperm number in the simple shear flow and the cross-stream migration velocity of sperm increases with the sperm number in a Poiseuille flow.

10:10AM H31.00011 Finite Element Modeling of Microswimmers with Applications in Reproductive Biology, CARA NEAL, DAVID SMITH, MEURIG GALLAGHER, THOMAS MONTENEGRO-JOHNSON, University of Birmingham — The journey of human sperm to the egg is a complex and extremely important process. Sperm cells must navigate the intricate geometry of the fallopian tubes, generating active bending to swim through cervical mucus - a highly viscous, rheologically complex fluid. Many current models of sperm locomotion are computationally expensive, and most make the inaccurate assumption that the surrounding fluid is Newtonian. Here we develop a method capable of dealing with the non-linear equations associated with non-Newtonian fluids. This method uses a combination of a finite element technique and an elasto-hydrodynamic integral formulation (Hall-McNair et al. 2019) to model sperm cells with active flexible flagella. This formulation provides an efficient way of modeling single or multiple cells, accounting for the hydrodynamic interactions between them. In particular, the finite element component is formulated in such a way that the solution can be calculated on a coarse mesh, for reduced computational costs compared to more commonly used body-fitted meshes. We study how the model can be made more biologically accurate through the inclusion of varying bending stiffness as well as a passive distal region of the flagellum, and the subsequent effect on swimming efficiency.

10:23AM H31.00012 Interaction of spermatozoa with micro structured surfaces, VASILY KANTSLER, University of Warwick, ANTON BUKATIN, St. Petersburg Academic University, ENKELEIDA LUSHI, New Jersey Institute of Technology, PETER DENISSENKO, University of Warwick — Spermatozoa navigation plays crucial role in the process of mammalian fertilization. Mechanical interactions in the heterogeneous environment of the fertility such as surface scattering and rheotaxis are the key mechanisms in determining the sperm journey towards the ovum. Here we report an experimental study of interaction mechanisms for single human sperm cells scattering off solid surface boundaries of different curvature. The investigation is based on measuring the trajectories of the cells near convex and concave surfaces with 30 ~ 300 um radii of curvature in a microfluidic device. By analysing several thousands of cells’ trajectories we built the residence time dependences, concentration profiles the scattering distributions as a function of the surface curvature. For the concave objects, we have identified the surface curvature corresponding to the minimum of the cell residence time within the concave centerline. We use sperm number, a dimensionless number representing the ratio of viscous force to elastic force, to study the effect of flagellar flexibility on the sperm trajectory. The length of the major axis of the elliptical trajectories increases with the sperm number in the simple shear flow and the cross-stream migration velocity of sperm increases with the sperm number in a Poiseuille flow.

8:00AM H32.00001 Approach to finite-size prey by the choanoflagellate Salpingoeca rosetta, KIARASH SAMSAMI, HENRY FU, University of Utah — The choanoflagellate S. rosetta is a unicellular eukaryote with a single flagellum and a collar of microvilli. It feeds on bacteria by utilizing the fluid currents generated by the beating of its flagellum that bring its prey to the surface of the collar and ingesting the bacterium. S. rosetta is observed as a single thecate cell, a single swimming cell, a rosette shaped colony with flagella pointing outwards, and a chain shaped colony with each cell attached laterally to two neighboring cells. As a close relative of animals, this ability to form colonies and the possible resulting survival advantages could provide insight on origins of multicellularity. Prior works have studied fluid uptake and flow fields for S. rosetta single cells and colonies as a measure of feeding performance. However the bacterial prey is comparable in size to the S. rosetta cell and hence may have a considerable effect on the flow in near field. Here we study the hydrodynamics of a single cell or a colony approaching a finite size prey, simulating actual geometries of both. We study the approach time and velocities of single cells and colonies for different prey sizes and initial positions to compare their feeding performance.
8:13AM H32.0002 Bacterial Motility Near a Surface. NICHOLAS COLTHARP, Trinity University — Bacteria spend much of their time in complex environments: colonies of bacteria form biofilms on surfaces, and even free-swimming bacteria may find their range of motion limited by their environment. To understand how they navigate through such environments, our first step is to construct a physically-realistic model of an E. coli bacterium. We then use the method of regularized Stokeslets and the method of images to compute its swimming speed, body rotation rate, and flagellar torque in a homogeneous viscous fluid. As we vary the distance of the model bacterium from a surface, our results agree well with those of other techniques, and with no experimental values. We also simulate a bacterium swimming in heterogeneous fluids with suspended microstructures such as elastic polymers and filamentous networks, similar to what real bacteria experience.

1Trinity University and NSF grant DMS-1720323

8:26AM H32.0003 In silico micro-swimmers: runs and tumbles. SOOKKYUNG LIM, University of Cincinnati — We present a mathematical model of a micro-swimmer E. coli that can freely run by a flagellar bundle and tumble by motor reversals. The Kirchhoff rod theory is used to model the elastic helical flagella and the rod-shaped cell body is represented by a hollow ellipsoid that can translate and rotate as a neutrally buoyant rigid body. The hydrodynamic interaction between the fluid and the bacteria is described by the regularized version of Stokes flow. In this talk, we will focus on how bacteria can swim and reorient the course of swimming and how parts of bacteria play a role in swimming.

8:39AM H32.0004 Swimming microalga as a micro-mixer in confined spaces. MOJTABA JARRAH, PEDRO ARANA-AGUDELO, Université Paris-Sud, LIMSI-CNRS, ADAMA CREPYY, Université Paris-Sud, FAST-CNRS, BEHNAM TAIIDI, CentraleSupélec - LGPM, HAROLD AURADOU, Université Paris-Sud, FAST-CNRS — The unicellular green alga Chlamydomonas uses two anterior flagella to swim in a breaststroke-like pulling motion, covering a distance of about seven to ten times its body size per second. This fast swimmer stirs the surrounding fluid like a mobile micro-mixer. How strong is this mixing? The few studies available on this subject, measured the diffusion of tracer particles around Chlamydomonas (a single cell or/and a suspension) to show mixing enhancement. However, we know that mixing process consists of folding and stretching of fluid elements. Diffusion of the tracer particles cannot be enough appropriate to characterize mixing features. In this work, we follow the separation of the tracers, initially close together, when swimming of a Chlamydomonas cell influences them. In this way, we quantify the mixing in different zones around the microswimmer. Some other aspects of the motility of Chlamydomonas in a confined environment, like residence time and light effects, are also investigated. Microscopy of Chlamydomonas and the tracers (Carboxylated yellow-green polystyrene microspheres, diameter = 0.5 μm) was carried out inside square bottom well arrays (125μm x 125μm x 60μm).

8:52AM H32.0005 Squirmer in a density-stratified fluid. VASEEM SHAIK, AREZOO ARDEKANI, Purdue University — In this work, we analyze the motion of a two-mode spherical squirmer in a linearly density stratified fluid using the method of matched asymptotic expansions. We assume that the quasi-steady conditions prevail, inertia is negligible, stratification and advective transport rate of density are small, and the swimmer is oriented either vertically upwards or downwards. We consider a swimmer that is either far away from its neutrally buoyant position (NBP) or close to its NBP. Using the Boussinesq approximation, we find that stratification reduces the speed of a swimmer that is far from its NBP irrespective of the swimming gait while the stratification reduces (resp. increases) the speed of a pusher (resp. puller) swimmer that is close to its NBP. We can understand the former observation by considering a settling rigid sphere in a stratified fluid whereas the latter observation is consistent with the reported direct numerical simulations. Close to the swimmer, the flow field is approximately the same in the homogeneous and the stratified fluid but far from the swimmer, the flow field in these two fluids is significantly different. We also comment on the power consumption and the swimming efficiency in a stratified fluid.

9:05AM H32.0006 Fibrous flagellar hairs of Chlamydomonas reinhardtii do not enhance swimming. GUILLERMO AMADOR, DA WEI, MARIE-EVE AUBIN-TAM, DANIEL TAM, Delft University of Technology — The flagella of Chlamydomonas reinhardtii possess fibrous ultrastructures of nanometer-scale thickness known as mastigonemes. While these structures are hypothesized to enhance flagellar thrust, detailed hydrodynamic evidence supporting this claim is lacking. In this study, we present a comprehensive investigation into the hydrodynamic effects of mastigonemes using genetically modified mutants lacking the fibrous structures. Through high speed observations of freely swimming cells, we found the average and maximum swimming speeds to be unaffected by the presence of mastigonemes. In addition to swimming speeds, no significant difference was found for flagellar gait kinematics. Following our observations of swimming kinematics, we present direct measurements of the hydrodynamic forces generated by flagella with and without mastigonemes. These measurements were conducted using optical tweezers, which enabled high temporal and spatial resolution of hydrodynamic forces. Through our measurements, we found no significant difference in propulsive flows due to the presence of mastigonemes. Direct comparison between experimental measurements and numerical simulations revealed that swimming hydrodynamics were accurately captured without including mastigonemes on the modeled swimmer’s flagella. Therefore, mastigonemes do not appear to increase the flagella’s effective area while swimming, as previously thought. Our results refute the claim that mastigonemes enhance flagellar thrust in C. reinhardtii, and so their function still remains enigmatic.

9:18AM H32.0007 Hydrodynamic and chemotactic influences in bacterial foraging. NIKHIL DESAI, VASEEM SHAIK, AREZOO ARDEKANI, Purdue University — The discovery that marine bacteria can break down the hydrocarbons in oil for nutrition has motivated a fundamental understanding of the mechanisms underpinning oil-microbe interactions, e.g., the effect of oil-water interfaces on the hydrodynamics of swimming microbes. Hydrodynamic interactions enable the passive capture of microswimmers around rigid/fluid spherical obstacles, which has important consequences on a bacterium’s ability to populate nutrient sources like marine snow, oil drops etc. In this talk, we first demonstrate theoretically, that surfactant-laden drops act as more effective hydrodynamic traps for bacteria than clean drops. Next, we explain the important differences between hydrodynamic trapping around stationary versus translating obstacles. Finally, we show how hydrodynamic interactions are complemented by chemotaxis to non-trivially alter the distribution of marine bacteria around both stationary oil drops and sinking marine snow particles effusing hydrocarbon/nutrient plumes. We thus delineate the effects of various physicochemical influences—like nutrient distribution, fluid-flow and proximity to interfaces—on microbial behavior in natural environments.
9:31AM H32.00008 Hydrodynamic essentials of flagellar bundling. ALEXANDER CHAMOLLY, ERIC LAUGA, University of Cambridge — A lot of recent research activity has addressed the swimming dynamics of prokaryotic cells, in particular the formation of bundles of helical flagella in bacteria such as E. coli. The exact dynamics of this process are complex, and most hitherto proposed computational models aiming for a detailed description have involved an interplay between a number of physical effects including long-range hydrodynamic interactions, elastic restoring forces and short-range steric interactions while respecting the overall force and torque balance between flagella and the cell body. In this study we aim to understand what fundamental physical mechanisms trigger bundle formation in the first place. We distinguish between active bundling, induced by hydrodynamic interaction of the flexible flagella with each other, and passive bundling, triggered by advection of fluid around a moving cell body. We propose a minimal analytical model that involves only the essential hydrodynamics of flagellar propulsion and show that it is able to predict the dynamics of bundling, as well as the relative strength of both hydrodynamic effects.

9:44AM H32.00009 A minimal model for Spiroplasma chemotaxis1, CHRISTIAN ESPARZA LOPEZ, ERIC LAUGA, University of Cambridge — Spiroplasma is a small helical bacterium that swims and performs chemotaxis in a non conventional way. Instead of actuating flagella, it swims by progressively shifting the chirality of its body. The change in geometry gives rise to a wall domain - a kink - which propagates along the cell body. The chirality is then reverted in a similar fashion completing a swimming stroke. The whole deformation is non-reciprocal in time, therefore movement at low Reynolds number is achieved with the bacterium moving in the direction opposite to the kink pair propagation. Based on experimental observations, we develop a minimal model to describe Spiroplasma chemotaxis. We start by a simple resistive force theory model of the bacterium swimming gait. Using symmetry arguments we show how to calculate the net rotation and translation of the bacterium during one full stroke. We obtain expressions for the linear displacement as a function of the time between kinks, , that compare favourably with numerical computations. Using our theoretical results, we then construct a random walk model for Spiroplasma and we obtain expressions for its diffusivity as a function of and the kink angle .

9:57AM H32.00010 Hydrodynamics of bacterial spinning top1, KENTA ISHIMOTO, Kyoto University — We have theoretically and numerically investigated mono-flagellated bacterial swimming dynamics near a wall boundary with considering elastic hook flexibility to understand hydrodynamic interactions underlying the bacterial upright spinning motion, which has referred as low-Reynolds-number spinning top in a recent experimental study. We establish an elastohydrodynamic stability theory and found that the vertical spinning motion is enabled by the mechanical competition between the destabilization by the flagellar propulsion and rotational stabilization by the elastic coupling of the hook. These results demonstrate the mechanical nature of the behaviours in rich diversity and could contribute to our deeper understandings of the bacterial surface motility and biofilm formation.

10:10AM H32.00011 Hydrodynamics of prey capture in ciliated microorganisms1, MADIS RODE, Department of Physics and Centre for Ocean Life, Technical University of Denmark, THOMAS KIJORBOE, National Institute of Aquatic Resources and Centre for Ocean Life, Technical University of Denmark, ANDERS ANDERSEN, Department of Physics and Centre for Ocean Life, Technical University of Denmark — Unicellular microorganisms play a key role in the biological processes in the ocean. Here we focus on the marine ciliate Euplotes vannus, which uses complex arrangements of cilia with periodic beat patterns to generate a feeding flow, retain prey particles, and transport the retained particles to the mouth region of the cell. We describe the hydrodynamics of prey capture to answer how the flow-rate of the feeding current and the prey size spectrum depend on motion and design of the organelles. We use particle image velocimetry to determine the feeding flow quantitatively, and particle tracking to identify retained and lost prey particles and to follow their transport to the mouth region. We have observed E. vannus to both swim freely and crawl or sit on solid surfaces. When freely swimming, the ciliate generates a puller-like flow field seemingly without feeding, and when sitting it generates a strong feeding flow that resembles the flow due to a point force at the front of the cell.

10:23AM H32.00012 Dynamics of growth and form in prebiotic vesicles, THOMAS FAI, Brandeis University, TERESA RUIZ-HERRERO, L. MAHADEVAN, Harvard University — The growth, form, and division of prebiotic vesicles, membraneous bags of fluid of varying components and shapes is hypothesized to have served as the substrate for the origin of life. The dynamics of these out-of-equilibrium structures is controlled by physicochemical processes that include the intercalation of amphiphiles into the membrane, fluid flow across the membrane, and elastic deformations of the membrane. To understand prebiotic vesicular forms and their dynamics, we construct a minimal model that couples membrane growth, deformation, and fluid permeation, ultimately coupled in terms of two dimensionless parameters that characterize the relative rate of membrane growth and the membrane permeability. Numerical simulations show that our model captures the morphological diversity seen in extant precursor mimics of cellular life, and might provide simple guidelines for the synthesis of these complex shapes from simple ingredients.

Monday, November 25, 2019 8:00AM - 10:36AM – Session H33 Flow Instability: Nonlinear Dynamics 615 - Thomas Ward, Iowa State University

8:00AM H33.00011 Linear stability analysis of a miscible two-layer power-law fluid in Couette flow1, THOMAS WARD, TEJASWI SOORI, Iowa State University — We examine the stability of a miscible two-layer power-law fluid in a 2D shear flow. The problem is motivated by recent experiments showing that miscible displacement of shear-thinning fluids yields an instability. To study fluid stability we analyze the mass, momentum and species conservation equations in a Couette flow geometry. Layer depth, consistency and power-law index are varied for zero wall slip conditions. We also examine the interface by treating the two-layer problem as a two-fluid one with zero surface tension. The governing equations are linearized about base states to estimate growth rates for dependent variables in the limit of infinitesimally small disturbances. We integrate the resulting ODE equations using a standard Chebyshev collocation method. We also compare results with prior ones for two-fluid layer and miscible two-layer problems, along with critical values observed in experiments.

8:13AM H33.00002 Exploiting noise-induced dynamics for system identification near a Hopf bifurcation

MINWOO LEE, The Hong Kong University of Science and Technology, YUANHANG ZHU, Brown University, YU GUAN, LARRY K.B. LI, The Hong Kong University of Science and Technology — We propose a system identification framework that exploits the noise-induced dynamics inherent to nonlinear systems near a supercritical or subcritical Hopf bifurcation. The key assumption made is that the system response can be modeled with a Stuart–Landau equation and its corresponding Fokker–Planck equation. We demonstrate the framework on two different flow systems: a hydrodynamic system (a low-density jet) undergoing a subcritical Hopf bifurcation, and a thermoacoustic system (a Rijke tube) undergoing a supercritical Hopf bifurcation. For both systems, we extract the model coefficients using experimental measurements of the noise-induced dynamics in only the unconditionally stable regime, prior to both the Hopf and saddle-node points. We show that the framework can accurately predict (i) the order of nonlinearity, (ii) the types and locations of the bifurcation points, and (iii) the limit-cycle characteristics beyond such points. As the noise-induced dynamics of nonlinear systems are expected to be universal in the vicinity of a Hopf bifurcation (Ushakov et al. 2005, Phys. Rev. Lett., vol. 95, 123903), the proposed framework should be applicable to a variety of flow systems in nature and engineering.

8:26AM H33.00003 The Role of Cubic Nonlinearity in Limit Cycle Oscillations of Variable-Density Shear Flows

CHRISTOPHER DOUGLAS, BENJAMIN EMERSON, TIMOTHY LIEUWEN, Georgia Institute of Technology — This work is directed toward understanding the limit cycle features of globally unstable flows with variable density. Analysis of limit cycles in constant-density shear flows have revealed that oscillation characteristics are controlled by two key effects: mean flow distortions and harmonic interactions. Both of these effects are manifestations of the quadratic nonlinearity of the incompressible Navier-Stokes equations, and their respective roles vary in different flow configurations. However, in flows such as bluff body wakes, surprisingly accurate predictions of important limit cycle features such as frequency and amplitude are possible by neglecting the latter effect and performing a linear analysis about the mean flow. Crucially, even when its amplitude is not small, the quadratic nonlinearity does not allow the limit cycle fundamental to directly modify itself. Conversely, when the fluid density is not constant, a cubic nonlinearity arises and enables self-interactions which are independent from the other effects. This calls into question the validity of linear approaches in such contexts and motivates an investigation of the role of these triadic self-interactions in variable-density shear flows.

8:39AM H33.00004 Nonlinear Fluid Flow Analysis Using Integral Quadratic Constraints

ANIKETH KALUR, PETER J. SEILER, MAZIAR S. HEMATI, University of Minnesota, Twin Cities — The exact mechanism for sub-critical transition to turbulence in shear flows is complicated and not fully understood due to the interaction between the linear and nonlinear terms in the Navier-Stokes equations (NSE). The linear operator in NSE causes a transient amplification of perturbation energy – a necessary condition for sub-critical transition. The nonlinearity in NSE acts in feedback with the linear system and mixes energy between modes. This static lossless nonlinearity is responsible for triggering transition and sustaining turbulence. In this talk, we will show that the nonlinearity in NSE can be replaced by a set of integral quadratic constraints (IQCs), which effectively represent correlations between the inputs and outputs of the nonlinearity. Thus, analysis of nonlinear flows can be cast as problems in the analysis of linear dynamics – coupling energy-based methods with corresponding IQCs. We perform our investigations on the Waleffe-Kim-Hamilton (WKH) model, which is a low-dimensional mechanistic model developed to capture the physics of transition. IQC-based stability and performance analysis of the WKH model will be presented.

8:52AM H33.00005 Effects of entry shapes on evolution and transition mechanisms of internal swirling flows

XINGJIAN WANG, Florida Institute of Technology, YANXING WANG, New Mexico State University — Previous works have investigated the characteristics of the central recirculation zone and intrinsic instability waves of a swirling flow injected through a tangential slit entry. In practice, orifice entry is frequently used to generate the swirling motion in a cylindrical chamber, but is much less documented. In this study, we numerically explore flow evolution and transition mechanisms of internal swirling flow with orifice entry using Galerkin finite element method. A grid convergence study is conducted to ensure the appropriate grid resolution at the orifice entry and in regions with complex flow structures. The effects of Reynolds number and swirl level controlled by the orifice angle are examined in detail. The numerical results of tangential slit and orifice entries will be compared systematically in terms of flow topologies and underlying instability mechanisms. A unified theory connecting different flow states of swirling flow will be established.

9:05AM H33.00006 On slow–fast generalized quasilinear dynamical systems

GREG CHINI, University of New Hampshire, ALESSIA FERRARO, Swiss Federal Institute of Technology Lausanne (EPFL), GUILLAUME MICHEL, Ecole Normale Superieure, CNRS, COLM-CILLE CAULFIELD, Cambridge University (DAMTP) — The quasilinear (QL) reduction has proved surprising useful in the analysis and modeling of anisotropic turbulent flows. As first introduced in the context of fluid turbulence by Stuart (1958), the QL approximation involves parsing flow variables into suitable (e.g., streamwise) mean and fluctuation fields and then retaining fluctuation-fluctuation nonlinearities only where they feed back onto the mean fields through Reynolds stress divergences. Although increasingly invoked as a useful albeit ad hoc approximation, the QL reduction can be formally justified in the asymptotic limit of temporal scale separation between the mean and fluctuation dynamics, as arises, e.g., in the asymptotic description of strongly stratified shear turbulence and of certain exact coherent states in wall-bounded shear flows. A fundamental and vexing feature of such systems, however, is that when the slow mean fields are locally frozen in time, the fast linearized dynamics can admit exponential fluctuation growth. In this work, a new multiscale formalism is introduced that obviates the need to co-evolve the mean and fluctuation dynamics on the fast time scale (i.e., the usual fix) by exploiting the necessity of slow–fast QL systems to self-tune toward a marginal-stability manifold.
9:18AM H33.00007 Stability of Flow past a Freely-Rotatable Sprung Cylinder. KE DING, ARNE PEARLSTEIN, Department of Mechanical Science and Engineering, University of Illinois at Urbana-Champaign — Recent work (Tumkur et al., J. Fluid Mech. 828, 196-235, 2017; Blanchard et al., Phys. Rev. Fluids, 4, 054501, 2019) considers flow past a linearly-sprung circular cylinder whose transverse rectilinear motion is inertially coupled to linearly-damped rotational motion of an attached mass about the cylinder axis. (The rotating mass is either inside the cylinder or beyond the span of the flow, thus having no contact with the fluid.) That work reveals chaotic response at Reynolds numbers (Re) well below the fixed-cylinder critical value $Re_{fixed,c}$ and multiple unsteady long-time solutions for many combinations of the parameters. Here, we consider flow past a linearly-sprung circular cylinder with a nonaxisymmetric density distribution, which is free to rotate, and whose rotational motion is linearly damped. As for the case where the cylinder cannot rotate, a steady, symmetric, motionless-cylinder (SSM) solution exists for all values of the parameters and all density distributions and orientations. We use a spectral-element technique to investigate the stability boundary in the space of Re and spring stiffness, and find that over a limited stiffness range, rotatability renders the SSM solution stable for Re >$Re_{fixed,c}$. We also show that stability boundaries for different (initial) orientations of the density distribution are very similar to those for different (initial) positions of the attached mass, suggesting that much of the complex dynamical behavior in the attached-mass case can be realized using a cylinder with nonuniform density, with no attached mass.

9:31AM H33.00008 Effect of electric field on the linear stability characteristics of two-layer channel of Newtonian and Herschel-Bulkley fluids. GAUTAM KUMAR, PURANAM ANANTH L NARAYANA, KIRTI SAHU, Indian Institute of Technology Hyderabad, India — We investigate the effect of electric field on the linear stability characteristics of pressure-driven flow in a channel, wherein a Newtonian fluid layer superposed on a layer of Herschel-Bulkley fluid. Both fluids are assumed to be incompressible and leaky dielectric media. The modified Orr-Sommerfeld eigenvalue problems are derived and solved using an efficient spectral collocation method. An asymptotic analysis is also performed in the long-wave limit. The effects of electric field, Bingham number, flow index and the ratios of density, viscosity, electrical conductivity and permittivity between the fluids are studied. We observed that the electric field can stabilize or destabilize the systems in different regimes.

9:44AM H33.00009 Genesis of Taylor–Couette Flow Instabilities, H. OUALLI, M. MEKADEM, M. KHIENNASS, Y. REZGA, S. TEBTAB, T. AZZAM, Ecole Militaire Polytechnique, Algiers, Algeria, A. BOUABDALLAH, Université des Sciences et de la Technologie Houari Boumediene, Algiers, Algeria, M. GAD-EL-HAK, Virginia Commonwealth University, Richmond, Virginia, USA — Numerical simulations are conducted of a Taylor–Couette flow from early structuring stages to completion of the Taylors axial stationary waves. We seek to elucidate the underlying mechanisms responsible for the genesis of this flow type and to identify the intermediate embryonic staged growth and completion of the Taylor and Couette rolls and cylinders are implemented on FLUENT. The calculations are based on the finite-volume method with a mesh size of 32×28×256 in, respectively, the radial, azimuthal, and axial directions. The simulations are validated using prior experimental results. The calculations span Taylor numbers from $Ta = 10^9$ to $Ta = 43.8$. The results show that the incipient pressure variations are of the order of $10^{12}$ Pa, detected at $Ta = 10^3$, on four symmetrically separated cardinal points within the system. When $Ta > 10^4$, a progressive propagation of alternating overpressure and depression zones operate in both azimuthal directions. This is the first step in the chain of mechanisms responsible for the Taylors wave building process. The study reports, for the first time, all the details to explain the instability mechanisms evolution.

9:57AM H33.00010 Linear and nonlinear thermosolutal instabilities in an inclined porous layer. PURANAM ANANTH L NARAYANA, GAUTAM KUMAR, KIRTI SAHU, Indian Institute of Technology Hyderabad, India — We investigate the double-diffusive instability in an inclined porous layer with a concentration based internal heat source by performing linear instability and nonlinear energy analyses. The effects of various dimensionless parameters, such as the thermal ($Ra_v$) and solutal ($Ra_c$) Rayleigh numbers, the angle of inclination ($\phi$), the Lewis number ($Le$), and the concentration based internal heat source ($Q$) have been investigated. A comparison between the linear and nonlinear thresholds for the longitudinal and transverse rolls provides the region of the subcritical instability. We found that the system becomes more unstable when the diffusivity of the temperature is larger than that of the solute and with an increase in the source strength. It is observed that increasing inclination angle stabilizes the system. Although the longitudinal roll remains stationary without the region of subcritical instability, the transverse roll transforms changes from stationary-oscillatory-stationary mode with the increase in the inclination angle.

10:10AM H33.00011 Stability of the interface of an isotropic active fluid1, WAN LUO, HARSH SONI, ROBERT PELCOVITS, THOMAS POWERS, Brown University — We study the linear stability of an isotropic active fluid in three geometries: a film of active fluid on a rigid substrate, a cylindrical thread of fluid, and a spherical fluid droplet. The active fluid is modeled by the hydrodynamic theory of an active nematic liquid crystal in the isotropic phase. In each geometry, we calculate the growth rate of sinusoidal modes of deformation of the interface. There are two distinct branches of growth rates: at long wavelength, one corresponds to the deformation of the surface, and one corresponds to the evolution of the liquid crystalline degrees of freedom. The passive cases of the film and the droplet are always stable. For these geometries, a sufficiently large activity leads to instability. Activity also leads to propagating damped or growing modes. The passive cylindrical thread is unstable for perturbations with wavelength longer than the circumference. A sufficiently large activity can make any wavelength unstable, and again leads to propagating damped or growing modes. Our calculations are carried out for the case of zero Frank elasticity. While Frank elasticity is a stabilizing mechanism as it penalizes distortions of the order parameter tensor, we show that it has a small effect on the instabilities considered here.

10:23AM H33.00012 The stability of evaporating binary liquid film heated from below1, ROBSON NAZARETH, School of Engineering, University of Edinburgh, GEORGE KARAPETAS, Department of Chemical Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, PRASHANT VALLURI, School of Engineering, Aristotle University of Thessaloniki, PEDRO SAENZ, Department of Mathematics, Massachusetts Institute of Technology, OMAR MATAR, Department of Chemical Engineering, Imperial College London, KHELLIL SEFIANE, P
The liquid water contains Sodium Fluorescein in concentrations below 168 ppm. Icicles exhibit ripples around their circumference with a near universal wavelength of 1 cm. Experiments have shown that the rippling instability is associated with small levels of impurities and is not present for sufficiently pure water. Existing models of icicle growth assume that the icicle is covered completely by a thin film of flowing water. In our work, we consider perturbations around this base state and employ Floquet-Bloch theory to account for disturbances of arbitrary wavelengths, i.e. not necessarily matching the periodicity of the substrate. Through numerical simulations, we highlight the effect of inertia, viscous, and capillary forces on the stability of the fluid flow and also examine in detail the effect of substrate wettability, orientation with respect to gravity and geometric characteristics of the substrate. Moreover, the existence of the freely moving contact lines inside the cavity gives rise to multiple steady states which are analyzed for their stability. The role of air inclusions in the stabilization of the liquid film and the related mechanism will be discussed.

The authors acknowledge the financial support from the LIMMAT foundation under the grant MuSiComPS and from the Hellenic Foundation for Research and Innovation (HFRI) and the General Secretariat for Research and Technology (GSRT), under grant agreements No 1743 and No 792.

We conclude that the roll-wave instability is analogous to the critical point of the roll-wave instability in a fluid film at Fr ≈ 1. We conclude that the roll-wave instability of the gravity current is responsible for the texture in a glass of Guinness beer.
9:18AM H34.00007 Bistability in the Flow of Polymer Solutions in Porous Media

CHRISTOPHER BROWNE, AUDREY SHIH, SUJIT DATTA, Department of Chemical and Biological Engineering, Princeton University — Polymer solutions are often injected in porous media to improve oil recovery or groundwater remediation, but applications are limited by an incomplete understanding of the underlying physics. In a tortuous pore space, the flow becomes unstable at sufficiently large injection rates. However, how the spatio-temporal characteristics of this flow state depend on pore geometry is poorly understood. We shed light on this question by systematically varying the spacing between pores. When the pore spacing is large, unstable eddies form upstream of each pore, similar to the case of an isolated pore. By contrast, when the pore spacing is sufficiently small, the flow exhibits a surprising bistability, stochastically switching between two distinct flow states. We hypothesize that this unusual behavior arises from the interplay between the retention of polymer strain between pores, hysteresis in polymer conformations, and fluctuations in the flow. Consistent with this idea, the mean flow state can be tuned by the imposed flow rate. Moreover, we find that while flow state is correlated between neighboring pores, these correlations do not persist long-range. Our results thus help to elucidate the rich array of flow behaviors that can arise in polymer solution flow through porous media.

9:31AM H34.00008 Elastic and Shear thinning instabilities for the flow of polymer solutions through microribbons

BIKHAN CHANDRA, VISWANATHAN SHANKAR, Indian Institute of Technology Kanpur — It is well known that the flow of dilute polymer solution through tubes undergoes a non-linear subcritical transition at Re slightly higher than 2000. However, when the polymer concentration is increased beyond a threshold concentration, the instability occurs at a Re much lower than 2000. The instability occurring at Re lower than 2000 at higher polymer concentration (hence higher elasticity) is a linear instability. A recent article by Poole, 2016, shows that if the polymer solution prepared is sufficiently shear thinning in nature, an instability occurs at very low inertia (Re<50). We explore the possibility of very low Re instability for the flow of concentrated polymer solutions through micro-tubes. High concentration of polymer solution coupled with small tube diameters enable us to reach high elasticity numbers. We observe that the polymer solution destabilize at very low Re (Re<10). The nature of instability is also observed to be very different as compared to elastio-inertial instability as observed from the scaling relationships.

9:44AM H34.00009 Soft Cell: Flow-induced deformation of a compliant Hele-Shaw cell

FINN BOX, School of Physics, University of Manchester, GUNNAR PENG, DAMTP, University of Cambridge, ANNE JUEL, DRAGA PIHLER-PUZOVIC, School of Physics, University of Manchester — We present an experimental study of the flow-induced deformation of a compliant Hele-Shaw cell, comprising a soft substrate and a rigid upper boundary separated by a thin gap. An axisymmetric displacement flow is formed by injecting viscous fluid, at a constant volumetric flux, into the center of the cell, which is pre-filled with the same fluid. By measuring the surface deformation of the substrate, we find that the deformation profile is self-similar during a period of transient growth before rapidly attaining a steady shape determined by the logarithmic profile of the fluid pressure within the cell. We discuss how the deformed substrate influences the motion of the advancing front between injected and resident file in the cell.

9:57AM H34.00010 Control of Radial Miscible Viscous Fingering Using a Finite Blob-An Experimental Study

SADA NAND, VANDITA SHARMA, MANORANJAN MISHRA, Indian Institute of Technology Ropar — We experimentally demonstrate the control of miscible viscous fingering instability in a novel way. We consider the less viscous fluid initially in a circular blob of finite radius r0 displacing the surrounding more viscous fluid in the radial Hele-Shaw cell. Experiments only with a point source (r0=0) are available in the literature. Getting initial finite circular blob is a huge experimental challenge. For each r0, a flow rate is wisely calculated so as to have a stable displacement up to radius r0. Also, a diligently designed T- junction is utilized in the Hele-Shaw experimental set-up to ease the fluid injection. The experiments depict the initial radius of the circular blob (r0) as a controlling parameter. A delay in instability is observed for experiments with non-zero r0 in comparison to those performed with a point source. Further, a reduced instability is evident with an increase in r0, which is in agreement with the numerical simulations performed.

8:00AM H35.00001 DEM Modeling of Coupled Multiphase Flow and Granular Mechanics: Wettability Control on Fracture Patterns

YUE MENG, BAUYRZHAN PRIMKULOV, Massachusetts Institute of Technology, ZHIHONG YANG, State Key Laboratory of Water Resources and Hydropower Engineering, Wuhan University, FIONA KWOK, University of Hong Kong, RUBEN JUANES, Massachusetts Institute of Technology — The interplay between multiphase flow in a granular medium and the displacement of the grain particles generates a wide range of patterns. The balance between frictional, viscous, and capillary forces has been studied in experiments and simulations, and has helped understanding the underlying mechanisms for a wide range of phenomena, such as methane migration in lake sediments. Here we study fluid-induced fracturing of granular media by hydromechanically coupling a moving capacitor dynamic network model with discrete element modeling. We inject a less viscous fluid into a frictional granular pack initially saturated with a more viscous, immiscible fluid under low capillary number. We study the impact of contact angle and initial packing density, and find four different regimes of the fluid invasion morphology: capillary invasion and fracturing, frictional fingers, capillary invasion, and capillary compaction. We rationalize these simulation outputs by means of a jamming analysis, which allows us to explain fracture initiation as emerging from a jamming transition. We synthesize the analysis in the form of a novel phase diagram of jamming for wet granular media.

8:13AM H35.00002 How the natural structure of cuttlebone facilitates efficient microfluidic transport

KARL FROHLICH, EHSAN EMSAILI, Cornell University, TING YANG, LING LI, Virginia Tech, SUNGHWAN JUNG, Cornell University — When a viscous fluid is displacing a less viscous fluid in a thin channel, the interface moves unevenly due to the Saffman-Taylor instability. Supressing such instability plays a key role in many petroleum industries and biological systems. One natural example of this phenomenon is in the bones of cuttlefish. These cuttlebones contain multiple parallel microscopic chambers which are reinforced by winding vertical wall-like structures. It has been studied that the cuttlefish regulates its buoyancy by pumping water in and out of this structure. In this study, we investigate the cuttlebone structure for its unique ability to suppress the instability of a moving liquid-gas interface. Cuttlebone samples were studied in vitro to understand how fluid moves through the structure at different pressures and flow rates. Additionally by using cuttlebone structure as biological inspiration, we fabricated simplified channels using 3D resin printing in order to more rigorously test the impact of the liquid-gas meniscus at varying channel curvatures, pressures and other arrangements. Results show that a presence in channel curvature and positioning, like that seen in cuttlebone, can prevent the uneven growth of menisci, helping to transport a liquid-gas interface more uniformly.

Barbara — Surfactants – molecules and particles that preferentially adsorb to fluid interfaces – play a ubiquitous role in industrial and biological
Tanner’s law suggested for spreading of a Newtonian fluid on solid substrates. We propose a scaling analysis based on a combination of the
extent to which, the spreading dynamics of the fluid contact-line on the solid substrate can affect the thinning dynamics of the fluid filament
formed between the needle and substrate. Experiments are performed using two flat substrates; a big substrate, where fluid contact-line in free
to move and a finite size substrate, where fluid contact-line is pinned. Two distinct flow regimes are observed. In regime I, the fluid wetting
dynamics does not significantly affect the filament thinning process. However, in regime II, the fluid wetting on the big solid substrate impacts
the filament thinning dynamics significantly by lowering the filament life time, extensional relaxation times and the Trouton ratios compared
to that of the pinned contact-line. Our analysis shows that spreading of these viscoelastic surfactant fluids are reasonably well captured by
Tanner’s law suggested for spreading of a Newtonian fluid on solid substrates. We propose a scaling analysis based on a combination of the
wetting forces and viscous dissipation that can successfully distinguish these two flow regimes from each other.

8:39AM H35.00004 Surface dilatational rheology during phase coexistence of insol-
uble surfactants , HARIHANKAR MANIKANTAN, University of California, Davis, TODD SQUIRES, University of California, Santa
Barbara — Surfactants – molecules and particles that preferentially adsorb to fluid interfaces – play a ubiquitous role in industrial and biological
flows involving fluid interfaces. Beyond reducing surface tension, surfactants may modify fluid flow by exerting Marangoni and/or surface
rheological stresses. Additional complexities often arise when insoluble surfactants exhibit non-trivial morphologies, for example, forming con-
densed phases with liquid crystalline order that coexist with disordered phases. Here, we show that the dynamic growth of liquid crystalline
domains at the expense of the continuous phase upon compression gives rise to a frequency-dependent viscoelastic behavior. We treat the
dynamic ‘freezing’ and ‘melting’ of insoluble surfactant domains as a 2D analog of classic works on dynamic adsorption and desorption of soluble
surfactants. Notably, our model predicts that liquid crystalline domains grow freely and the surfactant exerts no additional surface stresses
upon asymptotically slow compression. However, rate-dependent surface elasticity and surface viscosity emerge when the compression rate is
comparable to phase change rate.

8:52AM H35.00005 ABSTRACT WITHDRAWN —

9:05AM H35.00006 Size dependent droplet interfacial tension and surfactant trans-
port in oily bilgewater systems1 , YUN CHEN, CARI DUTCHER, University of Minnesota — Many liquid-liquid emulsions,
including shipboard oil bilge waters, are chemically stabilized by surfactants and additives. The emulsion stability is determined by the interfacial
tension (IFT) of surfactant-laden interface between the continuous and dispersed phase, as well as the size of the dispersed droplets. In the
present work, the dynamic IFT of droplets at micron-scale (~80 um) and milli-scale (~2 mm) is measured with simulated bilge waters with
soluble surfactant systems. It is found that the IFT of micron-scale droplets decays faster than that of the milli-scale droplets due to smaller
diffusion boundary layer thickness. When surfactants are added into aqueous phase for both water-in-oil and oil-in-water condition, the IFT of
micron-scale droplets decays faster when the surfactant is in outer phase than in the inner phase. In contrast, for the larger milli-scale droplets,
the IFT decay rate does not depend on which phase the surfactant is added. The observations are explained by the change in diffusion limited
to kinetic limited surfactant transport as the droplet size decreases. In addition, experimental results of droplet coalescence depending on the
IFT using model system is also presented in this work.

9:18AM H35.00007 Characteristics of wetting distance in multilayered paper-based
channel1 , HYUNWOONG KANG, Dept. of Mechanical Engineering, Hanyang University, ILHOON JANG, Institute of Nano Science and
Technology, Hanyang University, SIMON SONG, Dept. of Mechanical Engineering, Hanyang University — A multilayered paper-based device
which has a gap between paper layers can generate much greater flow velocity than a typical single layer paper-based device. This feature
enables quick analysis in applications utilizing paper-based devices. Predicting the time to reach the detection point and the amount of sample
fluid is critical to improving detection accuracy and manufacturing the multi-functional device. However, the multilayered paper-based device
has a more complicated fluid flow than the conventional device resulting in the different flow with the single-layer device that can be described
by the Lucas-Washburn equation. These are due to the simultaneous sample flow flowing through both gap and paper layer. For example, since
the paper internal flow is much slower than the gap internal flow, the fluid can be absorbed into the paper layer in the thickness direction, and
it reduces a flow rate, especially at the initial stage of the fluid flow. In this study, we analyze the characteristics of the flow mainly focused
on the differences between the existing capillary driven flow model and explain the factors that affect the wetting distance in the multilayer
paper-based channel.

9:31AM H35.00008 Flow topology and bifurcations in streaming lattices1 , YASHRAJ
BHOSALE, TEJASWIN PARTHASARATHY, GIRIDAR VISHWANATHAN, GABRIEL JUAREZ, MATTIA GAZZOLA, University of Illinois,
Urbana-Champaign — Viscous streaming flows generated due to constant curvature objects (circular cylinders, infinite plates) have been well-
understood in the past. Yet, characterization and understanding of such flows when multiple body length-scales are involved has not been
looked into. We propose a simplified setting to understand and explore the effect of multiple curvatures on streaming flows, analysing the
system through the lens of bifurcation theory. This analysis uncovers the dynamic richness of the system, which we showcase through potential
microfluidic applications.

9:44 AM H35.00009 Thermal behavior of slip length in connection with fluid-solid chemical affinity. ADRIANO GRIGOLO, THIAGO VISCONDI, JULIO MENEGHINI, Polytechnic School, University of São Paulo, IBERÊ CALDAS, Institute of Physics, University of São Paulo — The relation between fluid slip on a solid surface and flow temperature is investigated with the help of molecular dynamics simulations. An atomistic Couette configuration, consisting of a Lennard-Jones fluid and two rigid walls, is prepared and evolved to its steady state, where the slip length can be readily extracted from the linear velocity profile. Simulations are carried out for a broad range of temperatures and for different magnitudes of the fluid-solid chemical affinity. This last parameter is found to affect the overall shape of the slip length vs. temperature curve. Depending on its value, three distinct types of thermal behavior are observed: slips (unincreasing and decreasing), critical (constant), and sticky (increasing). We find that the temperature dependence of the slip length in each of these cases is well described by a simple heuristic function, whose adjustable parameters have a clear physical interpretation. The present study is aimed at the development of material-specific boundary conditions and their use in multiscale simulations. In this context, our analysis, once extended to more complex substances, may aid in the design and optimization of microfluidic devices and nanostructured membranes set to operate at specific temperatures.

9:57 AM H35.00010 Existence of the Navier slip condition for liquids. JESSE COLLINS, The University of Melbourne, SELIM OLCUM, Massachusetts Institute of Technology, DEBADI CHAKRABORTY, The University of Melbourne, SCOTT MANALIS, Massachusetts Institute of Technology, JOHN SADER, The University of Melbourne — The Navier slip condition is regularly used to characterize the interaction of a fluid with a solid boundary. Its use at the gas-solid boundary is justified rigorously from Boltzmann’s kinetic theory of gases, however no such parallel exists at the liquid-solid boundary. The strongest evidence for existence of the Navier slip condition at the liquid-solid interface comes from molecular dynamics simulations. As dictated by kinetic theory, the Navier slip length is a constitutive property that holds when the flow is continuum away from the solid interface. Here, we present an experimental protocol that is used to measure the Navier slip length on individual and isolated particles with exquisite precision. Experiments consisting of thousands of observations on individual gold nanoparticles give a constant slip length of $2.7\pm0.6$ nm — independent of particle size — providing experimental validation of the Navier slip condition for liquids.

10:10 AM H35.00011 Surface acoustic wave driven wetting transition. SUDEEPTHI A, ASHIS KUMAR SEN, Indian Institute of Technology Madras, LESLIE YEO, RMIT University, Australia — Water drop deposited on a nanostructured superhydrophobic surface undergoes wetting transition from Cassie-Baxter state to Wenzel state upon excitation by MHz frequency acoustic waves (surface acoustic waves). The wetting transition is governed by the competition between the input acoustic energy supplied to the drop via the surface acoustic waves (SAWs) and the energy barrier associated with the transition. The kinetic energy gained by the drop due to the transfer of energy from SAWs drive the liquid into the hydrophobic grooves to overcome the energy barrier associated with the replacement of low energy solid-gas interface with the high energy solid-liquid interface. As the liquid comes in contact with the substrate due to the filling of nanogrooves, boundary layer acoustic streaming assisted by the capillary flow in the hydrophilic bottom walled nanogrooves displaces the drop contact line giving rise to drop spreading. The transition is irreversible since the drop attains minimum energy state in the Wenzel condition.

10:23 AM H35.00012 In Situ Identification of Dewetting-Induced Large-Scale Deformation of Vertically Aligned Single-Walled Carbon Nanotubes. YUTA YOSHIMOTO, KOICHI ISOMURA, SOU SUGIYAMA, HUA AN, Department of Mechanical Engineering, The University of Tokyo, TAKUMA HORI, Department of Mechanical Engineering, Tokyo University of Science, TAIKI INOUE, SHOHEI CHIASHI, SHU TAKAGI, SHIGEO MARUYAMA, IKUYA KINEFUCHI, Department of Mechanical Engineering, The University of Tokyo — We investigated dynamical processes of capillary-mediated deformation of vertically aligned single-walled carbon nanotubes (VA-SWCNTs) via in situ observation of their wetting and dewetting behaviors using an environmental scanning electron microscope. Three types of wetting behaviors on a VA-SWCNT sample were observed, namely conical shaped water aggregates, spherical droplets on tips of conical shaped water aggregates, and extensively distributed water layers. The former two types both resulted in dimples on the VA-SWCNT surface, failing to induce large-scale deformation of VA-SWCNTs. In contrast, the latter caused the formation of wall-like structures and crack propagation in the VA-SWCNT film during the dewetting process due to directional retraction of vapor-liquid interfaces. Compared to the previous studies based on ex situ observations of dried samples, our in situ observation successfully captured temporal evolution of the dewetting-induced deformation, which represents initial stages of capillary processes that lead to the self-organization of VA-SWCNTs reported in recent literatures.

Monday, November 25, 2019 8:00 AM - 10:23 AM -
Session H36 Microscale Flows: Particles 618 - Michael Loewenberg, Yale University

8:00 AM H36.00001 Fiber buckling in confined viscous flows. ANKE LINDNER, JEAN CAPPELLO, OLIVIA DU ROURE, PMMH-ESPCI, PSL University, CNRS, Sorbonne University, Paris University, France, CAMILLE DUPRAT, Ladhyx, Polytechnique, France, MATHIAS Bichert, FRANÇOIS GALLAIRE, EPFL, Lausanne, Switzerland — Studying fluid structure interactions in confined flows is important to understand locomotion of micro-organisms in soils or medical conduct as well as the movement of long fibers in fractures, where they are used as in-situ probes for example in oil recovery. Here we look at the dynamics of a model system, constituted by flexible fibers freely transported in pressure-driven flows in a Hele-Shaw cell. Fiber height is comparable to channel height and in this very confined geometry the fiber dynamics are dominated by viscous friction with top and bottom walls. We focus on the dynamics of fibers oriented parallel to the flow direction and show that a buckling instability occurs under certain conditions. The fibers deform into a wavy shape resembling a wave-packet, with a well-defined dominant wavelength. Such an instability is triggered by a competition between viscous forces and elasticity and is observed only for long fibers, at least one order of magnitude larger than the observed wavelength. We characterize experimentally the instability and show that the wavelength of the deformation is proportional to an elasto-viscous length. We furthermore study the growth rate of the instability for different fiber geometries, flow strength, and mechanical properties of the fibers.

8:13AM H36.00002 Colloidal particle migration within microchannels in combined Poiseuille and electrokinetic flows, SHAURYA PRAKASH, VARUN LOCHAB, The Ohio State University — Recent discoveries show that dilute colloidal particle suspensions with diameters \(<1\mu m\) are assembled to distinct colloidal bands within microchannels (100 – 300µm wide x 34µm deep x 4cm long). Band formation requires opposing Poiseuille and electrokinetic flows. Band formation also requires a minimum applied potential threshold at a given shear rate. Band formation is a function of particle size and volume fraction, particle and channel wall zeta potential, electrolyte concentration, and the minimum electric field thresholds change non-monotonically for particle mixtures. Here, we discuss the broad parameter ranges to elucidate robustness of particle migration to and away from walls, formation of particle bands, and influence of fluid properties on particle migration and band formation. Interestingly, in co-flow with Poiseuille and electrokinetic flows, particles migrate away from the microchannel walls with aggregation near the bulk of the microchannel. Colloidal particle migration away from or towards the microchannel walls is likely due to the particle slip velocity with respect to the fluid. The particle migration is attributed to an electrohydrodynamic lift-like force, analogous to the inertial lift forces in sedimentation flows.

8:26AM H36.00003 Particle motion nearby rough surfaces, CHRISTINA KURZTHALER, AMIR PAHLAVAN, LAILAI ZHU\(^1\), HOWARD A. STONE, Department of Mechanical and Aerospace Engineering, Princeton University, NJ 08544, USA — Hydrodynamic interactions of particles with surrounding surfaces play a pivotal role in a variety of biological systems and microfluidic applications. Here, we study the motion of an externally driven particle through a viscous fluid along different boundaries that are characterized by periodic and rough surface shapes. We derive analytical expressions for the translational velocities of the particle using the Lorentz reciprocal theorem and find that the particle follows the surface shape, as anticipated by the time-reversal symmetry of Stokes flow. Moreover, our theoretical framework permits the statistical analysis of random rough surfaces, which do not affect particle motion on average but manifest themselves in the dispersion of particle trajectories. Our results are supported by numerical simulations using a boundary integral method and experimental observations. Overall, they should lay the foundation for our future understanding of microswimmer motion nearby random, heterogeneous boundaries.

8:39AM H36.00004 Hydrodynamic interactions between permeable particles, RODRIGO REBOUCAS, MICHAEL LOEWENBERG, Yale University — An analysis is presented for pairwise hydrodynamic interactions between permeable spherical particles in the limit of weak permeability, \(K = k/a^2 \ll 1\), where \(k\) is the permeability, and \(a\) is the reduced radius of the particles. Except for the near-contact motion of the particles, hydrodynamic interactions can be approximated by smooth spheres, the permeability having a weak perturbative effect under these conditions. However, non-zero particle permeability qualitatively affects the near-contact asymmetric motion, eliminating the classical lubrication singularity for smooth spherical particles. An integrodifferential lubrication equation incorporating Darcy’s law for flow inside the particles describes the near-contact motion of permeable spheres under weak permeability conditions. Collision efficiencies and hydrodynamic diffusivities are calculated and it is shown that permeable spherical particles are hydrodynamically equivalent to rough spheres with roughness \(\delta/a \approx K^{2/5}\).

8:52AM H36.00005 Spreading of diffusiophoretic colloids under transient solute gradients: Super-diffusion, trapping and shuttling\(^1\), HENRY CHU, Department of Chemical Engineering and Center for Complex Fluids Engineering, Carnegie Mellon University, Pittsburgh, PA 15213, United States, STEPHEN GAROFF, Department of Physics and Center for Complex Fluids Engineering, Carnegie Mellon University, Pittsburgh, PA 15213, United States — Diffusiophoresis (DP) refers to the deterministic drift of one species induced by a concentration gradient of another species. Recent microfluidic experiments have focused on DP of micron-scale colloids in gradients of small ionic solutes. A solute concentration gradient results in a DP colloid velocity \(\mathbf{u}_{\text{DP}} = M/\nabla \log S\), where \(M\) and \(S\) are the DP mobility and solute concentration, respectively. The mobility \(M\) can be positive or negative, corresponding to DP driving colloids up (solute-attracting) or down (solute-repelling) the solute gradient, respectively. Here, we calculate the advective-diffusive spreading of DP particles under transient solute gradients, highlighting novel transport phenomena for microscale sorting, deposition, and delivery of colloids. We show that evolution of an initial point source of colloids depends critically on the ratio of the DP mobility to solute diffusivity, with behavior ranging from spatial trapping for “solute-attracting” colloids, to long-time super-diffusion for “solute-repelling” colloids. Finally, a solute undergoing advective translation is shown to rapidly shuttle the colloids.

9:05AM H36.00006 Inertial bifurcation of the equilibrium position of a neutrally-buoyant circular cylinder in shear flow between parallel walls, ANDREW FOX, JAMES SCHNEIDER, ADITYA KAHR, Department of Chemical Engineering and Center for Complex Fluids Engineering, Carnegie Mellon University, Pittsburgh, PA 15213, United States — The dynamics of a neutrally-buoyant, rigid circular cylinder in shear flow between planar, parallel walls are quantified via various particle Reynolds numbers \(Re_p\) and confinement ratios \(\kappa\) via lattice Boltzmann simulations. An inertial lift force acting transverse to the ambient shear flow has a single zero crossing at the center of the channel below a critical \(Re_p\), corresponding to a single stable transverse equilibrium position. Above the critical \(Re_p\), the equilibrium position bifurcates, with an unstable equilibrium position at the center and two additional stable equilibria equidistant off-center. Trajectories of a force- and torque-free particle confirm the equilibrium position bifurcation, showing the cylinder reaches the center equilibrium position below the critical \(Re_p\) and the off-center equilibria above; the stable equilibrium position is independent of the initial cylinder position, with the lone exception of the aforementioned unstable equilibrium. The critical \(Re_p\) dependent on the confinement ratio, and thus particle size, and occurs below the transition to unsteady flow.

9:18AM H36.00007 inFocus: Fast Inertial Lift Velocity Calculation In Arbitrary Geometry\(^1\), SAMUEL CHRISTENSEN, grad student at UCLA, RAYMOND CHU, undergrad at UCLA, CHRIS ANDERSON, MARCUS ROPER, Professor at UCLA — Inertial microfluidic devices use inertial lift forces to arrange particles into required positions and formations. However, fully realized three dimensional simulations of inertial focusing require long computation times, making predictive device design very difficult. Here we use a combination of asymptotic methods and computational fluid dynamics to develop a fast, open-source fluid flow solver in Matlab that calculates particle dynamics in channels with arbitrary geometry. We use the new solver to dissect the contributions of shear and wall curvature to particle focusing with the goal of developing mechanistic understanding of how, where, and with what speed particles focus under inertial forces.

9:31AM H36.00008 High Frequency Inertial Particle Focusing. GIRDAR VISHWANATHAN, DIANZHOU WANG, GABRIEL JUAREZ, University of Illinois Urbana-Champaign — Inertial Focusing in micro-channels is a simple and reliable means of sorting, separating and controlling particle position, usually accomplished by producing steady flow in a long micro-channel. Recently, oscillatory flows have been shown to enable focusing of sub-micron particles, in much shorter channel lengths and at decreased pressure gradients even for frequencies < 20 Hz. Considering the substantial improvement of focusing efficiency even at relatively low oscillation frequencies, we present our experimental observations on the focusing of particles in the high frequency (20 – 1000 Hz) range. The role of the channel Womersley number on the focusing performance is critically examined.

9:44AM H36.00009 Solute-Driven Colloidal Particle Manipulation in Continuous Flows Past Microstructured channels. GUIDO BOLOGNESI, GORAN T. VLADISAVLJEVIC, Dept. of Chemical Engineering, Loughborough University, UK, FRANCOIS NADAL, Dept. of Mechanical Engineering, Loughborough University, UK, CECILE COTTIN-BIZONNE, CHRISTOPHE PIRAT, Universite Claude Bernard Lyon 1 - CNRS, France, NAVAL SINGH, Dept. of Chemical Engineering, Loughborough University, UK — Recent advancements in the chemical and biological analysis have led to the introduction of colloidal particle manipulation capabilities into microfluidic devices. Various active techniques have been employed for particle operations. The ability to manipulate particles by diffusion, a phoretic phenomenon leading to particle motion along a solute concentration gradient without the use of an external field, has gained an increasing attention. The aim of this study is to explore diffusiophoresis to enable particle filtration, trapping, and accumulation within a microfluidic environment under continuous flow settings. A microchannel, made of an optical adhesive and fitted with a micro-structured wall, was fabricated by photo-/soft-lithography. The charged fluorescent colloidal particles were accumulated within the channel microstructures by pumping electrolyte solutions into the device junction to generate salt concentration gradients. The spatial distribution of particles was characterized via confocal microscopy. This novel approach of particle handling in lab-on-a-chip device by solute driven transport can unlock potential applications in point of care industry, drug delivery and biosensing.

9:57AM H36.00010 Numerical Study of a Particle migration in a liquid-liquid stratified flow in a microchannel. T. KRISHNAVENI, T. RENGANATHAN, S. PUSHPAVANAM, Indian Institute of Technology, Madras — Inertial focusing is a passive separation technique in an axial flow where particles migrate laterally to equilibrium positions in the presence of finite inertia. These equilibrium positions mainly depend on the two counteracting forces namely the wall lift force and the shear gradient force. The equilibrium positions can be altered by changing the velocity profile of the fluid. In this work, we model the inertial focusing of a particle in the laminar, liquid-liquid stratified flow in a microchannel. This is used for the separation and recovery of cells from one fluid to the other without using any membrane. The particle is sent through one fluid and due to the shear gradient force and interfacial force, the particle may focus into the other fluid or stick at the interface. A flow between infinite parallel plates is considered to study the particle migration. An immersed boundary method coupled with the level set method is used to study the hydrodynamics and the particle dynamics. It is observed that the particle focus in the low viscous fluid beyond a critical flowrate ratio of two liquids. The effect of other parameters like phase holdup, Reynolds number, Weber number, particle size and wettability is analyzed on the particle migration.

10:10AM H36.00011 Spontaneous Lift of Particles Through Inhomogeneous Slip Surfaces in Lubricated Contacts. AIDAN RINEHART, UGIS LACIS, Royal Institute of Technology (KTH), THOMAS SALEZ, Laboratoire Ondes et Matiere d’Aquitaine (LOMA), SHERVIN BAGHERI, Royal Institute of Technology (KTH) — We reveal how inhomogeneous surfaces can accomplish wear reduction and increased mobility for particles traveling near walls. We consider a model problem of a cylinder near a wall where the surface (cylinder or wall) has non-homogeneous slip properties. We demonstrate that through variations in surface slip length the lubrication pressure symmetry is broken. Using lubrication theory we provide the analytical solutions to the hydrodynamic force and torques acting on the cylinder. Using numerical simulations, we also report various particle trajectories arising from inhomogeneous slip surfaces, including migration, agglomeration, and self-propulsion. We find a linear scaling between wall normal migration and slip length, $\Delta \sim l$, for wall parallel motion over a slip to no-slip wall transition. These findings are relevant especially for micro-fluidic and biological systems where particles typically reside in close proximity to walls.

Monday, November 25, 2019 8:00AM - 10:36AM – Session H37 Particle Laden Flows: Non-Spherical Particles 619 - S. Balachandar, University of Florida

8:00AM H37.00001 Comprehensive modeling of hydrodynamic forces and torques on non-spherical particles using the PIEP model. W. C. MOORE, S. BALACHANDAR, YUNCHAO YANG, University of Florida — The first aim of this work is to present a general formulation for the force and torque experienced by an isolated non-spherical particle. Then, a working model is introduced for a spheroid subject to uniform flow. To construct this model, particle resolved direct numerical simulations (PRDNS) of flow around a spheroid are performed for sub-critical Reynolds numbers. These PRDNS consider various angles of attack, rotational Reynolds numbers, and axes of rotation. The pairwise interaction extended point-particle (PIEP) model is then utilized to model a spheroid as three spheres, and extensions to other geometries, such as cubes as superposition of nine spheres, are being considered. Lastly, this model is used to predict the dynamics of a settling spheroid. The model’s results are compared to PRDNS results.

8:13AM H37.00002 Rotation rate of fibers in turbulence. CAUTIER VERHILLE, IRPHE - CNRS, ANKUR BORDOLOI, THERESA OEHMKE, Department of Civil and Environmental Engineering, UC Berkeley, IRPHE TEAM, UC BERKELEY TEAM — Since the last decade, more and more studies are devoted to the dynamics of anisotropic particles in turbulence. It has been shown theoretically and numerically that fibers smaller than the Kolmogorov length tend to align preferentially with the vorticity. More recently, Pujara et al. shows that longer fibers tend to align with the most extensional direction of the coarse grained velocity gradient. This difference of preferential alignment should have major impact on the rotational dynamics of particles: small fibers are expected to spin whereas long fibers are expected to tumble. We present here an experimental investigation on the global rotational dynamics (tumbling and spinning) of fibers smaller and larger than the Kolmogorov length. In this talk we will quantify the spinning and tumbling of fibers smaller and longer than the Kolmogorov length.

8:26AM H37.00003 Dynamics and wakes of freely settling and rising cubes. ANTHONY WACHS, University of British Columbia, ARMAN SEYED-AMMADI, Department of Chemical & Biological Engineering, University of British Columbia — In this investigation, we present numerical simulations of freely settling and rising cubes in a quiescent Newtonian fluid for various values of the Galileo number $70 \leq Ga \leq 250$ and of the solid-to-fluid density ratio $0.2 \leq \rho \leq 7$. Ultimately, we obtain a comprehensive two-parameter flow map for a freely moving cube and characterize prominent features of each regime of motion such as trajectories and wake structure. Unlike the case of a sphere, helical motion is observed for all density ratios, marking it as a characteristic type of motion for a cube. Furthermore, we present an in-depth force analysis relevant to the induced lateral motions, and we show that there is a significant jump in the drag coefficient coincident with the onset of the helical regime where large-amplitude lateral displacements appear. The enhancement of the drag coefficient is explained to be a combined effect of the vortex-induced drag and the orientation angle of the cube.

8:39AM H37.00004 Shape Dependence of Settling Velocities for Particles in Wavy Flows. LAURA CLARK, Stanford University, MICHELLE DIBENEDETTO, Woods Hole Oceanographic Institute, NICHOLAS OUELLETTE, JEFFREY KOSEFF, Stanford University — We investigated the effect of particle shape and oscillatory flow on the settling velocities of negatively buoyant particles with intermediate particle Reynolds numbers. In a laboratory wave tank, we tested a range of particle shapes, including discs, rods, and spheres, and wave characteristics, including shallow, deep, and intermediate surface gravity waves. By simultaneously measuring the velocities of the non-spherical particles and the fluid flow field, we extracted the instantaneous particle slip velocities, the statistics of how the particles preferentially sample the wave field, and their net settling velocities. We find that all of these quantities display a significant shape dependence.

8:52AM H37.00005 On the free-fall dynamics of highly inertial ellipsoids at $Re_p$ of $O(1)$. JOHANNES MILAN GÜTTLER, GHOLAMHOSSEIN BAGHERI, Max Planck Institute for Dynamics and Self-Organization — Much is still unknown about the dynamics of inertial ellipsoids as inertial non-spherical particles in turbulence lag behind the flow to adjust their orientation. In particular, it is not quantitatively understood how particles of different shapes orient themselves in turbulent flows and how fast their orientation responds to flow fluctuations. Experiments on single particles in a quiescent medium are the first step to characterize this. We present our work on freely falling ellipsoidal particles in the ‘intermediate’ regime of particle Reynolds number 1-10 using shadowgraphy in an air-filled column setup. The particles are well-defined and have volumes equivalent to a diameter 140 μm sphere, which became possible thanks to utilizing 2-Photon-Polymerization. The density ratio between the particles and the medium (air) is approx. 1000. The experiments were performed using three high-speed cameras to capture both the transient and the terminal state. This allows us to look into rotation/tumbling rates, terminal velocities and the transient dynamics: do stable fixed points in the orientation or oscillatory motions exist and is there a stable orientation that the particle will take? For particles with unstable transient orientation, what is the steady-state orientation?

9:05AM H37.00006 Taylor-Aris Dispersion of Elongated Rods. AJAY HARISHANKAR KUMAR, THOMAS POWERS, DANIEL HARRIS, Brown University — Particles transported in fluid flows, such as cells or nanorods, are rarely spherical in nature. In this study, we numerically and theoretically investigate the dispersion of an initial concentration of elongated rods in 2D pressure-driven shear flow. The rods translate due to diffusion and advection, and rotate due to rotational diffusion as well as their classical Jeffery’s orbit in shear flow. When rotational diffusion dominates, we approach the classical Taylor Dispersion result for the longitudinal spreading rate by using an orientationally averaged translational diffusivity for the rods. However, in the high shear limit, the rods tend to align with the flow and ultimately spread faster as a direct consequence of their anisotropic diffusivities. The relative importance of the shear-induced orbit and rotational diffusivity can be represented by a rotational Peclet number, and allows us to bridge these two regimes.

9:18AM H37.00007 Tuning the hydrodynamic interactions between non-uniform sedimenting particles. KAVINDA NISSANNA, XIAOLEI MA, JUSTIN BURTON, Emory University — Sedimentation dynamics of non-Brownian particles with non-uniform density distributions have recently been shown to exhibit hyperuniformity (Goldfriend et al., Phys. Rev. Lett., 2017). These predictions are tested here experimentally using spheroidal particles. Particles are classified by two parameters, their aspect ratio $\kappa$ and center of mass offset $\chi$. They were created from 2mm diameter spheres glued in various configurations. Spheres of different densities are used to vary $\chi$. We record the positions of particles using high-speed camera, as they sediment in a quasi-2D tank at $Re = 10^{-3}$. Using tracking algorithms, we reconstruct the sedimentation trajectories. Pair interaction between particles is characterized by particle center separation vs. vertical distance traveled. Particles with $\kappa > 1$ exhibit repulsive behavior, while particles with $\kappa < 1$ attract each other. Interaction strength is shown to be inversely proportional to $\chi$. For 3 or more simultaneously sedimenting particles, repulsive interactions lead to a more uniform distribution of particles positions, whereas attractive interactions lead to particle clustering.

Circulation significantly changes the flow topology into a bidimensional state so as to be responsible for the rotation rate variation.

The ratio shows a significant decrease. We propose a simple model to qualitatively understand the phenomenon. It is found that the large scale isotropic turbulence, the global rotation rate square for particles reveals a similar distribution whereas the averaged value as a function of aspect studies. Experiments as well as numerical simulations have highlighted their complex behavior, which is inherited from the non-trivial dynamics.

Flows, LEE WALSH, GREG VOTH, Wesleyan University — In a suspension of non-attractive rigid rods in a turbulent shear flow, we observe spontaneous aggregation into traveling clusters of high concentration. The fibers first accumulate in the turbulent boundary layer where they then break the symmetry of the apparatus by collecting into a few traveling clusters. The experimental apparatus is a Taylor–Couette cell whose floor and inner wall are rotating, and ceiling and outer wall are fixed. The heavy particles sediment downward and outward, so their concentration is highest near the junction of the rotating floor and the fixed outer cylindrical wall. With a multi-camera imaging system we can measure 3D fluid and fiber motion in the entire volume, and we are able to resolve individual fiber dynamics in the high-concentration regime where fiber-fiber interactions become important.

Time scale of rotation of inertial fibers in isotropic turbulence, ANKUR BORDOLOI, University of California Berkeley, GAUTIER VERHILLE, Aix Marseille Univ, CNRS, Centrale Marseille, IRPHE, EVAN VARIANO, University of California Berkeley — The past few years of research has significantly advanced our understanding of the rotational kinematics of inertial fibers in turbulence and their scaling with size. However, the question related to the time scale of rotational dispersion remains open. The time scale of rotation of inertial fibers is integral to processes such as paper-making, turbulent drag-reduction, fiber-glass blowing, and locomotion of planktonic organisms in the ocean. Based on time-resolved measurements of the orientation of rigid inertial fibers in a turbulence-tank, we compute a time scale \( \tau_1 \), fiber rotation. We show that this time-scale can be predicted by Kolmogorov’s inertial-range scaling based on fiber length \( L \) only when the diameter \( d \) is small. For fibers with large diameters, we invoke our previous theoretical model designed specifically for the variance of fiber rotation and find that it fails to predict \( \tau_1 \). We propose herein a new model that successfully predicts both these parameters for a wide range of \( L \) and \( d \).

Inertial Settling of Flexible Fiber Suspensions, MONA RAHMANI, University of British Columbia, ARASH ALIZAD BANAEI, KTH Royal Institute of Technology, MARK MARTINEZ, University of British Columbia, LIFENG JIANG, CHAO SUN,Tsinghua University, 100084 Beijing, China, ENRICO CALZAVARINI, Universite de Lille, F 59000 Lille, France — The rotational dynamics of small anisotropic material particles (e.g. fibers or disks) in turbulent flows has been the focus of a series of recent studies. Experiments as well as numerical simulations have highlighted their complex behavior, which is inherited from the non-trivial dynamics of the velocity gradient tensor along the particle trajectories. We report the investigation of orientation dynamics of neutrally buoyant anisotropic particles as they are advected in the Rayleigh-Benard convection by means of experiments and simulations. Compared with the homogeneous isotropic turbulence, the global rotation rate square for particles reveals a similar distribution whereas the averaged value as a function of aspect ratio shows a significant decrease. We propose a simple model to qualitatively understand the phenomenon. It is found that the large scale circulation significantly changes the flow topology into a bidimensional state so as to be responsible for the rotation rate variation.

Tumbling rate of anisotropic particles in turbulent convection, LINFENG JIANG, CHAO SUN, Tsinghua University, 100084 Beijing, China, ENRICO CALZAVARINI, Universite de Lille, F 59000 Lille, France — The rotational dynamics of small anisotropic material particles (e.g. fibers or disks) in turbulent flows has been the focus of a series of recent studies. Experiments as well as numerical simulations have highlighted their complex behavior, which is inherited from the non-trivial dynamics of the velocity gradient tensor along the particle trajectories. We report the investigation of orientation dynamics of neutrally buoyant anisotropic particles as they are advected in the Rayleigh-Benard convection by means of experiments and simulations. Compared with the homogeneous isotropic turbulence, the global rotation rate square for particles reveals a similar distribution whereas the averaged value as a function of aspect ratio shows a significant decrease. We propose a simple model to qualitatively understand the phenomenon. It is found that the large scale circulation significantly changes the flow topology into a bidimensional state so as to be responsible for the rotation rate variation.

A finite Re slender body theory, ANUBHAB ROY, Department of Applied Mechanics, Indian Institute of Technology Madras, Chennai 600036, India, DONALD L. KOCH, Smith School of Chemical and Biomolecular Engineering, Cornell University, Ithaca, NY 14853, USA — The effects of fluid inertia on the settling motion of fibers is studied theoretically. Khayat & Cox (1989) were the first to give a theory of hydrodynamic forces and torques on a slender body when fluid inertia is non-zero. Their theory uses a matched asymptotic expansion with a viscous inner flow and Oseens approximation for the outer flow. This restricts the analysis to cases where Re defined based on fiber diameter \( \text{Re}_D \) is zero. We develop a novel finite Re slender body theory that allows the inner flow to be described by steady Navier-Stokes and thus provide better comparisons of drag and torque with realistic scenarios where the \( \text{Re}_D \neq 0 \).

Monday, November 25, 2019 8:00AM - 10:36AM – Session H38 Porous Media Flow General I 620 - Chris MacMinn, University of Oxford

Soft porous lubrication with oriented fiber array, ZENGHAO ZHU, QIANHONG WU, Villanova University — The friction mitigating property of oriented fibrous materials is widely observed in nature. In this paper, we propose a novel theoretical model to predict the lubrication performance due to the gliding motion of a flat surface over a soft porous layer made of oriented fibers. The lubrication theory for highly compressible porous media is used to predict the lifting force from the fluid phase. The theory for large deformation of flexible beam is used to predict the lifting force from the solid phase. The results are validated numerically using Abaqus. The relative contribution of the fluid lifting force to the overall lifting force, fp, is then obtained, which is used as the criteria to evaluate the lubrication performance using soft porous materials. Dimensional analysis, along with a comprehensive parametric study have been performed to reveal the dominant factors that determine the lubrication performance. The study presented herein provides valuable guidance for applying highly organized porous media to soft porous lubrication.

1National Science Foundation, Award No. 1511096.
8:13AM H38.00002 Capturing gas in soft granular media. SUNGYON LEE, Department of Mechanical Engineering, University of Minnesota, Minneapolis, Minnesota, 55455, USA, JEREMY LEE, Department of Engineering Science, University of Oxford, Parks Road, Oxford OX1 3PJ, UK, FENG XU, Department of Mechanical Engineering, University of Minnesota, Minneapolis, Minnesota, 55455, USA, CHRISTOPHER MACMINN, Department of Engineering Science, University of Oxford, Parks Road, Oxford OX1 3PJ, UK — Gas migration through a soft granular material involves a strong coupling between the motion of the gas and the deformation of the material. We study this process experimentally by injecting air into a quasi-2D packing of soft particles and measuring the morphology of the air as it rises due to buoyancy. We systematically increase the confining pre-stress in the packing by compressing it with a fluid-permeable piston, leading to a gradual transition in migration mechanism from fluidization to pathway opening to pore invasion. By connecting these mechanisms quantitively with macroscopic invasion, trapping, and venting, we show that the mixed-mode transitional regime enables a sharp increase in the amount of gas trapped within the packing, as well as much larger venting events. We report our experimental findings and present a simple mechanistic model to rationalize our observations.

8:26AM H38.00003 Regularization of singularities at corners in two-dimensional Darcy flows1, ALEXANDER BELOZEROV, NATALIA PETROVSKAYA, YULII SHIKHMURZAEV, School of Mathematics, University of Birmingham, UK — As can easily be shown, for flows past wedges protruding into a porous medium the standard Darcy model produces unphysically singular velocities, thus over-predicting the flow rate and making impossible to describe some flows, e.g. involving wetting fronts, where the pointwise distribution of velocity has to be modelled realistically. A seemingly obvious remedy of smoothing out corners does not apply as, in the real life, the radius of curvature of the tips of such corners can easily be on the pore scale, i.e. zero on the Darcy scale. A recent study (AIChE J. 63(2017)5207) introduces an approach to the problem where, following a suggestive physical analogy, the permeability even of a spatially uniform porous matrix with respect to a flow is, at every point, a function of the curvature of the flow streamline at this point, decreasing as the curvature increases. This preserves the Darcy model for unidirectional flows, where it has been well-tested, and regularizes 2D flows, where the flow field and the distribution of permeability now become intertwined and have to be found simultaneously. The new class of models brings in a fundamentally new class of numerical problems. In the present work, we develop a method of handling such problems and highlight some outstanding issues.

8:39AM H38.00004 A comprehensive experimental and analytical study of fluid flow in a thin porous layer under indentation.1, QIUYUN WANG, ZENGHAO ZHU, QIANHONG WU, Villanova University — In this paper, we report a novel experimental and theoretical approach to examine fluid flow in a thin porous layer during an indentation process. Experimentally, a custom-designed indenter with the precisely controlled nano-positioning system is developed where the local compression of the porous layer is captured by a high-speed camera. The indenter is fully instrumented with a laser displacement sensor to measure the indentation velocity and pressure transducers to measure the pore pressure distribution. Theoretically, a consolidation theory is developed where the local relative velocity between the fluid and solid phase is considered, and the local compression-dependent permeability dependent on the indentation velocity. Excellent agreement between the experimental results and the theoretical predictions is observed under different running conditions, verifying the validity of the theory. The study precisely captures the detailed non-uniform compression of a thin porous layer under indentation. It provides a conclusive theoretical framework in the study of fluid flow in a soft porous media, laying the foundation for the study of soft porous matter in response to indentation.

1NSF CBET fluid dynamics program, #1511096

8:52AM H38.00005 The hydraulic conductivity of shaped fractures with permeable walls1, DAIHUI LU, IVAN C. CHRISTOV, School of Mechanical Engineering, Purdue University, West Lafayette, Indiana, 47907 — We derive the hydraulic conductivity $K$, i.e., the proportionally constant between the width-averaged velocity field and the pressure gradient in Darcy’s law, for shaped fractures with permeable walls. As a model, we study a tapered Hele-Shaw cell, with a width gradient $dh/dx = \alpha$ in the flow direction, and porous boundaries. The permeable walls are treated using the Beavers–Joseph slip boundary condition. Using lubrication theory, we obtain $K$, accounting for geometric non-uniformity and leakage into the bounding surfaces. The approach is perturbative, giving both the leading-order term (independent of the Reynolds number $Re$) and the first correction in $Re$. Thus, our theory gives $K$ in terms of hydraulic parameters such as $Re$, geometric parameters such as the fracture’s width $h(x)$ and $\alpha$, and the dimensionless slip coefficient $\phi$ at the porous walls. Previous research has not addressed the joint dependence on $Re$ and $\alpha$. Specifically, our calculations show that, quantitatively, $Re$ has a comparable effect to $\phi$ on the value of $K$, for $\alpha \neq 0$. Finally, we use the open-source computational fluid dynamics software, OpenFOAM, to perform 3D direct numerical simulations to benchmark and verify our mathematical predictions.

9:05AM H38.00006 Stochastic Modelling of Sieving in Membrane Filters with Complex Pore Morphology1, BINAN GU, New Jersey Institute of Technology, PEJMAN SANAEI, New York Institute of Technology, LOU KONDIC, LINDA CUMMINGS, New Jersey Institute of Technology — Membrane filters have been widely used in industrial applications to remove contaminants and undesired impurities from the solvent. During the filtration process the membrane internal void area becomes fouled with impurities and as a consequence the filter performance deteriorates. In addition to the internal morphology of membrane filters, fouling mechanisms contribute to the complexity of the filtration process, in deterministic or stochastic ways. So far various models have been proposed to describe the membrane structure and stochasticity of particles flow individually but very few focus on both together. In this work, we present a model, in which a membrane consists of a series of bifurcating pores, which decrease in size as the membrane is traversed and particles are removed from the feed by adsorption within pores and sieving simultaneously. We derive a probabilistic formulation of the sieving process using a continuous-time Markov chain. Lastly, we discuss how filtration efficiency depends on the characteristics of the branching structure and show the coupling between the two fouling mechanisms.

1NSF-1615719
9:18AM H38.00007 Upscaled models for heterogeneous reactions in porous media¹, MATTEO ICARDI, FEDERICO MUNICCHÌ, University of Nottingham — Although the basic understanding of the macroscopic limit of linear advection diffusion reaction equations is well understood since the early developments of porous media theory, its extension to complex flow regimes is still currently an open question, even in presence of well-separated spatial scales. This is due to the presence of non-trivial microscopic equilibrium configurations (compared to the trivial constant solution obtained by standard periodic homogenisation), or of dynamic equilibrium configurations. For example, when dealing with fast surface reactions, large microscopic gradients can develop locally. Similarly, a conservative solute in the vicinity of a concentration source (injection) undergoes a dynamic evolution of the local microscopic configuration in time and space before reaching the asymptotic self-similar profile. These are only two examples when the classical upscaling approaches fail, and effective macroscopic equations are often found either empirically or by resorting to generic random walk models. In this talk, we present some (old and) new theoretical frameworks to overcome these limitations, by computing local spectral properties (eigenvalues and eigenfunctions) of the underlying transport operators.
